Die Dissertation wurde am 01.07.2019 bei der Technischen Universität München eingereicht und durch die Fakultät Wissenschaftszentrum Weihenstephan für Ernährung, Landnutzung und Umwelt der Technischen Universität München am 11.10.2019 angenommen.

## ABSTRACT

Inflammatory bowel diseases (IBD) are associated with compositional and functional changes of the intestinal microbiota, but specific contributions of individual bacteria to chronic intestinal inflammation remain unclear. *Enterococcus faecalis* is a resident member of the human intestinal core microbiota that has been linked to the pathogenesis of IBD and induces chronic colitis in susceptible monoassociated IL10-deficient (IL-10<sup>-/-</sup>) mice. In this study, we characterized the colitogenic activity of *E. faecalis* as part of a simplified microbial consortium based on human strains (SIHUMI).

RNA sequencing analysis of *E. faecalis* isolated from monoassociated wild type and IL-10<sup>-/-</sup> mice identified 408 genes including 14 genes of the ethanolamine utilization (*eut*) locus to be significantly upregulated in response to inflammation. Despite considerable upregulation of *eut* genes, deletion of ethanolamine utilization ( $\Delta$ *eutVW*) had no impact on *E. faecalis* colitogenic activity in monoassociated IL-10<sup>-/-</sup> mice. However, replacement of the *E. faecalis* wild type bacteria by a  $\Delta$ *eutVW* mutant in SIHUMI-colonized IL-10<sup>-/-</sup> mice resulted in exacerbated colitis, suggesting protective functions of *E. faecalis* ethanolamine utilization in complex bacterial communities.

To better understand *E. faecalis* gene response in the presence of other microbes, we purified wild-type *E. faecalis* cells from the colon content of SIHUMI-colonized wild type and IL10<sup>-/-</sup> mice using immuno-magnetic separation and performed RNA sequencing. Transcriptional profiling revealed that the bacterial environment reprograms *E. faecalis* gene expression in response to inflammation, with the majority of regulated genes not being shared between monocolonized and SIHUMI conditions. While in *E. faecalis* monoassociation a general bacterial stress response could be observed, expression of *E. faecalis* genes in SIHUMI-colonized mice was characterized by up-regulation of genes involved in growth and replication. Interestingly, in mice colonized with SIHUMI lacking *E. faecalis* enhanced inflammation was observed in comparison to SIHUMI-colonized mice, supporting the hypothesis that *E. faecalis* ethanolamine metabolism protects against colitis in complex consortia.

In conclusion, this study demonstrates that complex bacterial consortia interactions reprogram the gene expression profile and colitogenic activity of the opportunistic pathogen *E. faecalis* towards a protective function.

## ZUSAMMENFASSUNG

Chronisch entzündliche Darmerkrankungen gehen mit kompositionellen und funktionellen Veränderungen der Darmmikrobiota einher, allerdings ist der spezifische Beitrag einzelner Bakterien zum entzündlichen Geschehen weitgehend unklar. *Enterococcus faecalis* ist ein residentes Mitglied der menschlichen Darmkernmikrobiota, das mit der Pathogenese chronisch entzündlicher Darmerkrankungen in Verbindung gebracht wird und chronische Kolitis in suszeptiblen monoassoziierten IL10-defizienten (IL-10<sup>-/-</sup>) Mäusen induziert. In dieser Studie haben wir die kolitogene Aktivität von *E. faecalis* als Teil eines vereinfachten mikrobiellen Konsortiums basierend auf menschlichen Stämmen (SIHUMI) charakterisiert.

Eine RNA-Sequenzierungsanalyse von *E. faecalis* Zellen, die aus monoassoziierten Wildtyp- und IL-10<sup>-/-</sup>-Mäusen isoliert wurden, identifizierte 408 Gene, darunter 14 Gene des Ethanolaminverwertungs-Locus (*eut*), die als Reaktion auf Entzündungen signifikant hochreguliert werden. Trotz erheblicher Hochregulierung der *eut*-Gene hatte die Deletion der Ethanolaminverwertung ( $\Delta$ eutVW) keinen Einfluss auf die kolitogene Aktivität von *E. faecalis* in monoassoziierten Mäusen. Der Austausch des *E. faecalis* Wildtyp-Stammes durch eine  $\Delta$ eutVW-Mutante in SIHUMI-kolonisierten IL-10<sup>-/-</sup>-Mäusen führte jedoch zu einer Verschlimmerung der Entzündung. Dies deutet auf eine protektive Funktion der Ethanolaminverwertung durch *E. faecalis* in einer komplexen Gemeinschaft hin.

Um die Genexpression von *E. faecalis* in Gegenwart anderer Mikroben besser zu verstehen, haben wir Wildtyp-*E. faecalis*-Zellen aus dem Darminhalt von SIHUMI-kolonisierten Wildtyp- und IL-10<sup>-/-</sup>-Mäusen mittels immunomagnetischer Trennung isoliert und mittels RNA-Sequenzierung analysiert. Die transkriptionelle Analyse ergab, dass das bakterielle Umfeld die Genexpression von *E. faecalis* in Reaktion auf Entzündungen neu programmiert. Nur ein kleiner Teil der regulierten Gene waren sowohl in *E. faecalis* in Monoassoziation, als auch in Co-Kolonisation mit dem SIHUMI Konsortium parallel reguliert. Während bei monoassoziiertem *E. faecalis* eine allgemeine Stressreaktion beobachtet werden konnte, war das Expressionsprofil von *E. faecalis* in SIHUMI kolonisierten Mäusen durch Gene gekennzeichnet, die an Wachstum und Replikation beteiligt sind. Interessanterweise führte die Kolonisation von IL-10<sup>-/-</sup> Mäusen mit SIHUMI unter Ausschluss von *E. faecalis* zu einer Verschlimmerung des inflammatorischen Phänotyps. Dies unterstützt die Hypothese, dass *E. faecalis* als Mitglied eines komplexen Konsortiums durch die Verwertung von Ethanolamin eine protektive Funktion in suszeptiblen IL-10<sup>-/-</sup> Mäusen vermittelt.

Abschließend zeigt diese Studie, dass Interaktionen mit einem komplexen bakteriellen Konsortium das Genexpressionsprofil und die kolitogene Aktivität des opportunistischen Pathogens *E. faecalis* in Richtung einer protektiven Aktivität umprogrammieren.

# 1. INTRODUCTION

## 1.1 IBD – a multifactorial chronic disease associated with a westernized lifestyle

Inflammatory bowel diseases (IBD) with the two dominant types Crohn's disease (CD) and Ulcerative colitis (UC) are chronic relapsing inflammatory disorders affecting the gastrointestinal (GI) tract. CD is characterized by discontinuous, transmural inflammation occurring most commonly in the terminal ileum and colon (Baumgart and Sandborn, 2012). In UC, inflammation is restricted to the colon and only affects the mucosal surface. Tissue inflammation always begins at the rectum and extends continuously in the proximal direction (Ordas et al., 2012).

Both diseases are on the rise worldwide, with the highest incidence rates in westernized countries. While developing countries had a low incidence of IBD, incident rates increased with increasing industrialization of those countries, indicating a strong influence of environmental factors on the onset of disease (Loftus, 2004; Molodecky et al., 2012). Several factors appear to be involved in the pathogenesis of IBD, including genetic susceptibility (Jostins et al., 2012) and diverse environmental triggers resulting in an inappropriate T-cell mediated activation of immunity towards components of the intestinal microbiota (Xavier and Podolsky, 2007; Sartor, 2008). The environmental triggers of disease identified so far include smoking, diet, antibiotics, nonsteroidal anti-inflammatory drug use, stress and infection. However, the mechanisms underlying disease initiation by these factors are not well understood. It has been suggested that environmental triggers influence intestinal barrier integrity, immune responses or the luminal microenvironment, eventually leading to an inflammatory response in a genetically susceptible host (Sartor, 2006).

It is well established that genetic factors influence the susceptibility to IBD with an increased risk of disease in relatives of IBD patients. The degree of heritability is different for disease subtypes with a lower genetic component in UC compared to CD (Moller et al., 2015). This is consistent with monozygotic twin studies, which show a concordance rate of only 10–15% in UC compared to 30–35% in CD (Spehlmann et al., 2008; Brant, 2011). To date, more than 230 single nucleotide polymorphisms (SNPs) associated with an increased risk for IBD have been identified by genome-wide association studies (Turpin et al., 2018). The majority of these SNPs appear for both UC and CD, indicating a common genetic basis for the IBD subtypes, with multiple genes contributing to disease risk (Jostins et al., 2012).

Many genetic risk loci associated with IBD development are involved in the modulation of host immune responses towards intestinal microbes including bacterial recognition and clearance, intestinal barrier function and cellular stress responses. These defects can lead to a loss of tolerance to commensal microbiota, together with the inability to down-regulate immune responses after

exposure to luminal antigens, resulting in relapsing inflammation with chronic tissue damage (Sartor, 2008; Jostins et al., 2012).

## 1.2 Physiologic Microbe-Host Interactions

The control of the intestinal microbiota with a dynamic balance between immune recognition and defense seems to play a central role in IBD pathogenesis. Usually, the commensal microbiota and the host coexist in a mutualistic relationship that has been established through co-evolution. The GI tract hosts a diverse community of bacterial species with bacterial counts ranging from very low levels in the stomach up to  $10^{12}$ /g in the colon. The human gut microbiota is a dynamic ecosystem consisting of an estimated 400-1000 bacterial species with large variations between individuals, especially for less abundant species (Qin et al., 2010; Donaldson et al., 2016). However, most people share a core set of microbially encoded genes and thus metabolic core functions provided by the microbiome (Turnbaugh et al., 2009; Human Microbiome Project, 2012).

The commensal microbiota confers metabolic functions beyond those of the host alone and enables the host to obtain energy from dietary compounds that would otherwise be indigestible. Some bacterial metabolites, such as short-chain fatty acids (SCFA), are not only an important source of energy but also influence intestinal barrier function and immune responses (Turnbaugh et al., 2006; Kau et al., 2011; Marchix et al., 2018). In addition, the endogenous commensal microbiota competes with invading microorganisms for nutrients and space, thus providing a colonization resistance against incoming pathogens (Sorbara and Pamer, 2018).

The mucosal surfaces of the GI tract are constantly exposed to microbial antigens derived from the diverse community of endogenous bacteria, underlining the importance of maintaining immune tolerance to commensal microbiota while combating pathogens. This balance between tolerance and defense is mediated through extensive microbe-host interactions. The commensal microbiota is essential for the development and function of the host immune system. Vice versa, a functioning host immune system is essential for maintaining a symbiotic relationship with the microbiota by maintaining mucosal homeostasis. The immune system of germfree animals is underdeveloped with hypoplastic Peyer's patches, a greatly reduced number of IgA-producing plasma cells and CD4+ T-cells in the lamina propria, poorly matured spleen and lymph nodes and reduced serum IgG levels. All these defects can be reversed by colonization of GF animals with a complex commensal microbiota (Bauer et al., 1963; Benveniste et al., 1971; Macpherson et al., 2001; Macpherson et al., 2002).

A key strategy of the host to maintain mucosal homeostasis is to maintain a spatial separation between the microorganisms and the host. A single cell layer of intestinal epithelial cells (IECs) separates the large number of intestinal microorganisms from underlying tissues. This barrier is

further enhanced by a mucus layer, the production of IgA by plasma cells and the secretion of antimicrobial peptides (AMPs) by Paneth cells (Macpherson and Uhr, 2004; Johansson et al., 2008; Bevins and Salzman, 2011; Johansen and Kaetzel, 2011). These reinforcement strategies minimize the contact between microorganisms and the epithelial cell surface, thereby limiting immune overactivation and microbial translocation.

Goblet cells secrete mucin glycoproteins, the constituents of the intestinal mucus layer which restricts the access of microorganisms to the epithelial surface. While the mucus in the small intestine consists of a single layer that allows the microbes to get into contact with the epithelium, a structurally different bi-layer forms in the large intestine. Herein, the inner mucus layer is impenetrable for most microorganisms, while the outer mucus layer provides a habitat for a large number of bacteria (Johansson et al., 2011).

A second line of defense against microorganisms is provided by the production of AMPs. AMPs have antimicrobial functions including the disruption of bacterial cell wall or inner membrane. (Hooper and Macpherson, 2010). A small number of bacteria that overcome the host's first line defense mechanisms and breach the epithelial barrier are killed by macrophages or processed by dendritic cells (DCs) that promote the induction of secretory IgA. Secretory IgA can be produced by both T-cell independent (innate IgA) and T-cell dependent mechanisms (adaptive IgA). The local secretion of innate IgA limits penetration and overgrowth of microbiota, but is not as potent as adaptive IgA in shaping microbiota composition and with this a mutualistic relationship between host and microbiota (Kawamoto et al., 2014; Sutherland et al., 2016).

It is hypothesized that enteric pathogens induce the production of specific high-affinity IgA, whereas commensal species induce low-affinity IgA with low specificity (Pabst, 2012; Slack et al., 2012). Interestingly, it was demonstrated that high IgA-coating identifies indigenous bacterial species, which trigger intestinal inflammation (Palm et al., 2014). Furthermore, certain commensal bacteria induce systemic IgA, which confers protection against polymicrobial sepsis. This supports the hypothesis that IgA has an important function in maintaining immune homeostasis (Wilmore et al., 2018).

In healthy hosts, commensal bacteria stimulate a program of immune responses that is dominated by homeostatic mechanisms such as down-regulation of microbe-sensing receptors and secretion of anti-inflammatory molecules that terminate immune responses and mediate mucosal barrier function (Sartor, 2008). Some of these mechanisms are controlled by the sensing of microbes or microbe-derived products by the host. Bacterial recognition depends on a repertoire of pattern recognition receptors (PRR) expressed by IECs and innate immune cells residing in the lamina propria. The activation of these PRR by bacterial ligands stimulates central signaling cascades such as

nuclear factor- $\kappa$ B (NF- $\kappa$ B) and mitogen-activated protein kinase (MAPK) pathways resulting in the expression of pro- or anti-inflammatory proteins (Sartor, 2008).

The integration of these multiple signals by IECs and immune cells ensures the homeostasis of the tissue and the integrity of the barrier at the interface between the microbiota and host tissue. Disorders of this tightly balanced system can lead to the development of a chronic overactivation of the host's immune system characteristic for IBD.

## **1.2 Importance of microbe-host interactions in IBD pathogenesis**

Several lines of evidence, including clinical and experimental studies, suggest that microbial agents play a central role in the pathogenesis of IBD (Figure 1). The most convincing evidence is the absence of inflammation in several rodent models that are genetically susceptible to chronic immune-mediated intestinal inflammation when kept under germfree (sterile) conditions (Hormannsperger et al., 2015). In addition, genes related to innate immune recognition and response are enriched among IBD risk loci, which suggests that defects in intestinal microbiota containment increase IBD susceptibility (chapter 1.2.1). CD and UC occur mainly in the colon and distal ileum, the intestinal areas with the highest bacterial concentrations and the diversion of the fecal stream prevents and treats CD (Sartor and Mazmanian, 2012).

Furthermore, it has been shown that the composition and function of the microbiota in IBD patients is altered compared to healthy controls. These alterations are referred to as dysbiosis. Among the dysbiotic changes characteristic for IBD are a reduced bacterial diversity associated with the expansion of supposedly harmful microbes combined with a loss of supposedly protective microbes (chapter 1.2.2) (Sartor and Wu, 2017). The functional relationship between IBD pathogenesis and the intestinal microbiota is further illustrated by substantial T-cell and serologic responses to a variety of microbial antigens in IBD patients indicating defective immune regulation after microbial stimulation (Mow et al., 2004; Sartor, 2008; Harmsen et al., 2012).

**Figure 1: Microbe-Host interactions in IBD pathogenesis.**

IBD etiology involves genetic susceptibility, environmental triggers, and the gut microbiome. Bacterial antigens and microbe-associated molecular patterns (MAMP's, e.g. lipoproteins, lipopolysaccharide) are processed by host receptors (TCR, T-cell receptor; PRR, pattern recognition receptor) and induce inappropriate T-cell mediated activation of immunity towards components of the intestinal microbiota leading to inflammation and tissue damage. The intestinal microbiota is influenced in diversity, composition and function by internal (inflammation, genetic factors, microbe-microbe interactions) and environmental factors (e.g. diet, antibiotics). Alterations of the microbial ecosystem that are associated with pathology are defined as dysbiosis.

### 1.2.1 Host genetic defects in the containment of intestinal microbes

The strongest genetic risk factor associated with CD is the nucleotide-binding oligomerization domain 2 (NOD2) gene. The NOD2 gene encodes a cytoplasmic PRR that senses muramyl dipeptide, a component of the peptidoglycan present in bacterial cell walls (Hugot et al., 2001; Ogura et al., 2001; Girardin et al., 2003). IBD-associated mutations of the NOD2 locus are thought to cause defective bacterial recognition accompanied by impaired NF- $\kappa$ B activation, Paneth cell function (reduced defensin production) and finally clearance of intracellular pathogens (Bonen et al., 2003; Hisamatsu et al., 2003; Wehkamp et al., 2004; Kobayashi et al., 2005).

It has also been reported that NOD2 controls the commensal microbiota composition. In NOD-deficient mice, increased bacterial load and reduced capability to prevent colonization with pathogenic bacteria were observed (Petnicki-Ocwieja et al., 2009). This is consistent with a study from Frank and colleagues showing that NOD2 polymorphisms were associated with shifts in microbiota composition in CD patients (Frank et al., 2011).

Other IBD susceptibility loci affecting microbial recognition and killing include ATG16L1, IRGM, NCF4 and TLR receptors. ATG16L1 is an integral protein of the autophagy pathway involved in the clearance of intracellular pathogens (Rioux et al., 2007; Cadwell et al., 2008). In line with this, IRGM plays a role in killing of phagocytosed bacteria and is associated with abnormal Paneth cell morphology (Singh et al., 2006; Roberts et al., 2008; Liu et al., 2013). NCF4 is a component of NADPH oxidase and crucial for the production of reactive oxygen species by phagocytic cells (Rioux et al., 2007; Roberts et al., 2008). TLR receptors identified as IBD risk loci include TLR2, 4 and 5. These PRRs sense bacterial lipoproteins, lipopolysaccharide and flagellin, respectively (Beutler, 2000; Pierik et al., 2006; Meena et al., 2013; Chassaing et al., 2014).

### 1.2.2 Dysbiosis of the intestinal microbiota

Alterations of the microbial ecosystem that are associated with pathology are defined as dysbiosis. Characteristic dysbiotic changes reported for IBD are a reduced microbial diversity, an expansion of supposedly pathogenic bacteria and a loss of supposedly protective species. There is evidence that dysbiosis can be both cause and consequence of intestinal inflammation. This will be discussed in detail in the following section.

A causative role is supported by a therapeutic efficacy of antibiotics, probiotics and fecal microbiota transplantation (FMT) in some IBD patients. All these treatment strategies target the dysbiotic microbiota. Antibiotics remove large communities of bacteria, while probiotic treatment and FMT attempt to correct a dysbiotic ecosystem by introducing new and potentially beneficial bacterial species (Hansen and Sartor, 2015). Narrow-spectrum antibiotics like metronidazole and ciprofloxacin provide some benefit to CD patients, while UC patients seem to benefit only from broad antibiotic combinations (Hansen and Sartor, 2015).

The use of probiotics like *E. coli* Nissle and the probiotic combination VSL#3 appears to maintain and possibly induce remission in a number of UC patients (Rembacken et al., 1999; Kruis et al., 2004; Sood et al., 2009; Tursi et al., 2010). So far, however, no beneficial effect of probiotic treatment has been observed for CD (Kruis, 2013). FMT treatment appears to induce remission in a subset of UC patients. However, additional studies are needed to support these findings and the optimal composition of donor microbiota and FMT conditions (mode and intensity of administration) need to be defined (Hansen and Sartor, 2015; Moayyedi et al., 2015; Rossen et al., 2015; Costello et al., 2017; Paramsothy et al., 2017). Another strong evidence of dysbiosis as a cause of IBD is the induction of colitis in wild type (WT) mice through the transfer of fecal microbiota from mice suffering from colitis (Elinav et al., 2011).

In contrast, there is also convincing evidence that the dysbiosis observed in IBD is the consequence of inflammation, antibiotic treatment or diet (Lewis et al., 2015). Active IBD and experimental chronic intestinal inflammation are associated with changes in bacterial community composition (Gevers et al., 2014; Berry et al., 2015; Schaffler et al., 2016; Osaka et al., 2017) and gene expression (Patwa et al., 2011; Tchapchet et al., 2013; Ocvirk et al., 2015).

Schaffler and colleagues were able to show that the mucosa-attached bacterial community of CD patients is related to disease state, with dysbiotic changes being associated with high disease activity scores (Schaffler et al., 2016). Gevers and colleagues also observed a strong correlation between the dysbiotic status of the intestinal microbiota and the disease activity in new-onset CD patients (Gevers et al., 2014). In accordance with this, a recent study by Schirmer and colleagues demonstrated that the severity of the baseline disease in new-onset UC patients is associated with the depletion of core gut microbes and the expansion of oral bacteria (Schirmer et al., 2018).

Dysbiotic changes occurring in a chronic inflammatory environment are characterized by a reduced bacterial diversity, a reduction of obligate anaerobic bacteria such as SCFA-producing Ruminococcaceae and Lachnospiraceae and an expansion of facultative anaerobic bacteria from the phylum Proteobacteria, mainly belonging to the family Enterobacteriaceae (Baumler and Sperandio, 2016; Duvallet et al., 2017; Pascal et al., 2017). These changes are likely to reflect alterations in the nutritional environment and epithelial defense mechanisms by the inflammatory host response.

A prominent hypothesis that attempts to explain the shift from obligate to facultative anaerobic bacteria, is referred to as the “Oxygen hypothesis” (Rigottier-Gois, 2013). It has been suggested that intestinal inflammation is associated with an increase in intraluminal oxygen concentrations due to hyperemia and increased vascular and mucosal permeability. O<sub>2</sub> would inhibit the growth of oxygen-sensitive obligate anaerobes and at the same time serve as an electron acceptor for facultative anaerobes and thereby promote their growth. In the mouse intestine, a radial gradient of microbes linked to oxygen levels was observed, wherein aerotolerant bacteria were enriched at the mucosa, while anaerobic microbes dominate the intestinal lumen. (Rigottier-Gois, 2013; Albenberg et al., 2014; Sartor and Wu, 2017). In accordance with the “Oxygen hypothesis”, new-onset CD patients exhibit an altered mucosal bacterial community with a higher number of aerotolerant species than healthy controls (Gevers et al., 2014; Haberman et al., 2014).

A central mechanism that shapes the bacterial community is nutrient availability. It has been shown that mucosal inflammation is associated with dysregulated epithelial electrolyte transport. In mice, the disruption of a Na<sup>+</sup>/H<sup>+</sup> exchanger caused dysbiosis of the gut microbiota and microbiota-dependent inflammatory symptoms (Laubitz et al., 2016). In addition, the production and

composition of mucus is altered in inflammatory processes (McGuckin et al., 2011). A change associated with inflammation is an increase in carbohydrate fucosylation. Fucose from mucus carbohydrates can be liberated and utilized by members of the gut microbiota, providing a growth advantage for these species (Baumler and Sperandio, 2016). In line with this, mucosa-associated bacteria are increased in IBD, with a disproportionate enrichment of some mucus-degrading bacteria (Png et al., 2010). For instance, *Ruminococcus gnavus*, a known utilizer of mucin glycans, appears to be particularly enriched in CD patients (Prindiville et al., 2004; Willing et al., 2010; Joossens et al., 2011; Crost et al., 2013).

Another mechanism that supports the bloom of certain members of the microbiota during inflammation-associated dysbiosis is the production of alternative respiratory electron acceptors as by-product of inflammatory host responses. Alternative electron acceptors such as nitrate or tetrathionate promote the anaerobic respiration of some facultative anaerobes. Anaerobic respiration enables the utilization of non-fermentable substrates or fermentation end products as carbon sources. This confers facultative anaerobes a fitness advantage over obligate anaerobes that lack the necessary genes and can lead to their uncontrolled expansion in the intestinal lumen (Winter et al., 2010; Thiennimitr et al., 2011; Winter et al., 2013; Winter and Baumler, 2014).

An example is the bloom of *Salmonella enterica* serovar Thyphimurium (*S. Thyphimurium*) in the inflamed intestine through the utilization of Ethanolamine (EA) upon tetrathionate respiration (Thiennimitr et al., 2011). EA is derived from the membrane phospholipid phosphatidylethanolamine by microbial activity and can be used by some bacteria as valuable source of carbon and/or nitrogen. Most species that are able to utilize intestinal EA are pathogens, the only commensals that contain the necessary genes are *Enterococcus faecalis* (*E. faecalis*) (chapter 1.5) and some strains of *Escherichia coli* (*E. coli*) (Tsoy et al., 2009; Kaval and Garsin, 2018; Rowley et al., 2018).

Inflammation alters not only the nutritional environment, but also epithelial defense mechanisms such as the generation of reactive oxygen (Harper et al., 2005; Haberman et al., 2014) and nitrogen species (Lundberg et al., 1994; Salzman et al., 1996) as well as the production of antimicrobial molecules and IgA (Ramanan and Cadwell, 2016). All this influences the composition of the bacterial community by providing a fitness advantage for bacterial species that can quickly adapt to and take advantage of this particular environment.

Interestingly, several bacterial species showing an altered frequency during active IBD affect immune responses in experimental colitis models either by mediating homeostasis or inflammation. A prominent indicator species lost in IBD is *Faecalibacterium prausnitzii* (*F. prausnitzii*), a member of the Clostridiaceae family. *F. prausnitzii* was found specifically decreased in microbiota samples of IBD

patients compared to healthy specimens (Ramanan and Cadwell, 2016) and the low-mucosal abundance of this species was associated with post-resection relapse of CD (Sokol et al., 2008). It has been shown that *F. prausnitzii* and other Clostridium species exert positive immune suppressive effects on the host, including the suppression of experimental colitis and the induction of T-regulatory cells (Treg cells) (Sokol et al., 2008; Atarashi et al., 2013). Together with the decline of protective species, the expansion of potentially pathogenic species is characteristic for an IBD-associated dysbiotic microbiota.

However, the significance of correlation analyses is limited. Bloom et al. isolated Bacteroides and Enterobacteriaceae species from spontaneously colitic dnKO mice. In these mice, the abundance of Bacteroides was not altered compared to noncolitic control animals, whereas Enterobacteriaceae were strikingly enriched in spontaneous disease. Surprisingly, colonization of antibiotic-treated dnKO mice with Bacteroides isolates induced colitis, whereas colonization with Enterobacteriaceae isolates did not (Bloom et al., 2011). Similar results were also obtained by Perez-Munoz et al. in TM-IEC C1galt1(-/-) mice. Monoassociation with a *Lactobacillus johnsonii* isolate, that was found to be enriched in colitic TM-IEC C1galt1(-/-) mice, did not induce disease (Perez-Munoz et al., 2014).

Bacterial species that are usually blooming under inflammatory conditions are not classical pathogens, but mostly commensal species with functional alterations. Intestinal inflammation creates a special environment that boosts the growth of those species that are well adapted and resistant to immune defense mechanisms. Under homeostatic conditions, these “opportunistic pathogens” are commensal members of the microbiota, but can have detrimental inflammation-promoting effects in immune-compromised hosts.

Adherent and invasive *E. coli* (AIEC) were found in high prevalence in the mucosa of patients with ileal CD (Darfeuille-Michaud et al., 2004). Baumgart et al. showed that invasive *E. coli* are restricted to inflamed mucosa in ileal CD patients and that their number correlates with disease severity (Baumgart et al., 2007). AIEC use different strategies to interact with the host to promote bacterial growth and survival. AIEC strongly adhere to and invade IECs, leading to pro-inflammatory cytokine secretion. Furthermore, they can survive and replicate within macrophages, thereby inducing a strong TNF- $\alpha$  response (Agus et al., 2014). Bacterial adhesion to IECs is mediated via the interaction of bacterial type1 pili with the host receptor carcinoembryonic antigen-related cell adhesion molecule 6 (CEACAM6) (Barnich et al., 2007) or via binding of the bacterial ChiA protein to the host chitinase 3-like-1 receptor (Low et al., 2013). CEACAM6 has been shown to be highly expressed in ileal IECs of CD patients and in a transgenic mouse expressing human CEACAMs to mimic the situation in CD patients, the AIEC reference strain LF82 induced the development of colitis (Carvalho et al., 2009). AIECs can actively resist against AMPs and translocation across the epithelial barrier is

mediated by different mechanisms, including the modulation of tight junctions. Furthermore, AIEC outer membrane vesicles interact with the endoplasmic reticulum (ER) stress response glycoprotein Gp69 that is over-expressed in the apical IEC membrane in CD patients (Agus et al., 2014).

A second species often mentioned in the context of IBD pathogenesis is Gram-positive *E. faecalis*. Enterococci have been found to be increased in fecal samples from CD patients compared to healthy controls (Kang et al., 2010; Shiga et al., 2012; Zhou et al., 2016). This is consistent with an increased frequency of *E. faecalis* housekeeping as well as virulence genes in CD cohorts (Roche-Lima et al., 2018) and a high likelihood of *E. faecalis* isolates from inflamed IBD mucosa to carry virulence genes (Golinska et al., 2013).

UC patients show an increased number of mucosa-associated *E. faecalis* correlating with disease activity (Fite et al., 2013) and high *E. faecalis* specific IgG reactivity (Furrie et al., 2004). *E. faecalis* induces chronic colitis in monoassociated IL-10-deficient mice (IL-10<sup>-/-</sup> mice), a well characterized model to mimic human colitis (Balish and Warner, 2002; Barnett et al., 2010). In previous studies we could assign the colitogenic activity of *E. faecalis* to certain bacterial structures, suggesting that the contribution of bacteria to IBD pathogenesis depends on microbe-host interactions via specific structures (Steck et al., 2011; Ocvirk et al., 2015). This makes the situation even more complex, as these structures are often strain-specific and their degree of expression can be regulated in response to environmental cues (chapter 1.4).

### **1.3 Animal models of experimental colitis: Microbe-Host interactions**

Animal models are a useful tool to study microbe-host interactions and their role in the pathogenesis of IBD without confounding factors such as diet, genetic background and the microbial environment. The development of intestinal inflammation in animal models can be triggered either by a chemical inductor (e.g. DSS or TNBS) or preferably by genetic background. Many genetically driven IBD mouse models are disease-free when kept under GF conditions and clearly demonstrate the importance of microbial triggers for IBD pathogenesis.

The IL-10<sup>-/-</sup> mouse, incapable of producing the anti-inflammatory cytokine IL-10, is an extensively studied model of spontaneous colitis. GF housed IL-10<sup>-/-</sup> mice are free of disease, while mice colonized with a complex microbiota develop chronic intestinal inflammation (Sellon et al., 1998). Colitis development in IL-10<sup>-/-</sup> mice is mediated by an abnormal response of Th1/Th17 cells to microbial triggers leading to massive production of pro-inflammatory cytokines such as IFN $\gamma$ , IL-12 and IL-17 (Berg et al., 1996; Davidson et al., 1996; Yen et al., 2006). It is noteworthy that disease

onset and severity depend on the microbial environment, the time of colonization and the genetic background (Sellon et al., 1998; Mähler M, 2002; Kim et al., 2005).

Monoassociation studies (colonization of GF mice with a single bacterial strain) revealed that not all microorganisms, even including some opportunistic pathogens like *Helicobacter hepaticus*, trigger inflammation in IL-10<sup>-/-</sup> mice. This demonstrates that some species have higher colitogenic activity than others (Whary et al., 2011) (Figure 2). Of note, species that trigger colitis in one experimental colitis model may not necessarily induce disease in other experimental models (Hormannsperger et al., 2015). For example, *Bacteroides vulgatus* induces inflammation in monoassociated HLA/B27-β2m rats, but not in IL-10<sup>-/-</sup> or IL-2<sup>-/-</sup> mice (Rath et al., 1999; Sydora et al., 2005; Frick et al., 2006). Monoassociation of IL-10<sup>-/-</sup> mice with different strains of *E. coli* or *E. faecalis* was sufficient to induce disease supporting the colitogenic character of these species (Balish and Warner, 2002; Kim et al., 2005; Kim et al., 2007; Patwa et al., 2011). However, the absence of disease in monoassociated WT animals indicates that these species are not pathogens.

**Figure 2: Impact of microbial colonization on disease development in gnotobiotic IL-10<sup>-/-</sup> mice**

Interestingly, the location of inflammation and onset of disease varies from species to species. *E. faecalis*-driven inflammation develops primarily in the distal colon with only a weak phenotype in the cecum, while *E. coli*-driven inflammation is most pronounced in the cecum (Kim et al., 2005). This demonstrates that different bacterial species can induce variable inflammatory phenotypes in a

single susceptible host. Geva-Zatorsky et al. screened in an elaborate study 53 human-derived microbes for their immunomodulatory activities in gnotobiotic WT mice. They were able to show that the majority of microbes analyzed induced immunophenotypic and/or transcriptomic changes in the host, with only a few bacteria having no influence on the host organism according to the parameters measured. Most microbes elicited a distinct immunophenotype, but the effects could be redundant and even complementary. Surprisingly, the immunophenotypic and transcriptomic effects were independent of microbial phylogeny (Geva-Zatorsky et al., 2017).

Since the microbiota of conventional animals is too complex to dissect the mechanisms of disease development, gnotobiotic animals colonized by a defined simplified microbial consortium are used as a model system to mimic the conditions in conventional hosts. This allows the manipulation of the bacterial community and its individual members, which is crucial for studying the complex interactions between microbes themselves and between microbes and their host.

Brugiroux et al. have established a defined mouse consortium comprising 12 bacterial isolates that provides partial colonization resistance against *S. Typhimurium* infection. Reinforced with 3 facultative anaerobes selected according to functional characteristics, the consortium provided complete colonization resistance to *S. Typhimurium* (Brugiroux et al., 2016). This shows that a simplified microbial consortium can mimic a complex microbiota in terms of colonization resistance. However, the composition of the consortium is important. Furthermore, it should be noted that gnotobiotic mice colonized with a simplified microbial consortium may be morphologically and functionally similar to conventional mice, but so far there is no minimal consortium available that fully restores all functions conducted by a conventional microbiota (Becker et al., 2011; Eun et al., 2014; Hormannsperger et al., 2015; Brugiroux et al., 2016).

A simplified human microbiota consortium (SIHUMI) has been shown to induce antigen-specific colitis in gnotobiotic IL-10<sup>-/-</sup> mice (Eun et al., 2014). The SIHUMI consortium is composed of 7 well-characterized species of human origin known to show shifts in the microbiota of IBD patients. In gnotobiotic animals, SIHUMI forms a stable community with the abundance of individual SIHUMI species being influenced by host genetic background and the presence of intestinal inflammation. In IL-10<sup>-/-</sup> mice, the individual bacterial strains induce differential effector immune responses with no direct correlation to bacterial abundance (Eun et al., 2014).

#### **1.4 *E. faecalis* as model organism for microbe-host interactions in IBD**

*E. faecalis* is a Gram-positive resident member of the human intestinal core microbiota, but also carries a number of pathogenic traits that explain the association of this bacterium with IBD and fatal nosocomial infections (Qin et al., 2010; Sava et al., 2010; Lebreton et al., 2014). This dualistic

character as an opportunistic pathogen makes *E. faecalis* an exemplary model for the investigation of microbe-host interactions that are relevant for the pathogenesis of chronic colitis.

In the IL-10<sup>-/-</sup> mouse model, monoassociation with *E. faecalis* causes severe colitis that is characterized by a defective resolution of TLR-2 mediated pro-inflammatory gene expression in the intestinal epithelium (Ruiz et al., 2005). We were able to show that the colitogenic activity of *E. faecalis* in monoassociated IL-10<sup>-/-</sup> mice can be assigned to certain bacterial structures (Steck et al., 2011; Ocvirk et al., 2015). The secreted protease Gelatinase E (GelE) impairs intestinal barrier integrity by cleavage of the epithelial tight junction protein E-cadherin, which promotes the development of chronic inflammation in susceptible IL-10<sup>-/-</sup> mice (Steck et al., 2011). Furthermore, we found that enterococcal polysaccharide antigen (epa) influences biofilm formation and *in vivo* mucus penetration, which partially contributes to disease development, while functional *E. faecalis* lipoproteins involved in TLR2-mediated activation and recruitment of innate immune cells are required as primary bacterial structures responsible for *E. faecalis* colitogenic activity (Ocvirk et al., 2015).

### 1.5 Ethanolamine utilization in *E. faecalis*

The ability to catabolize EA is encoded by the *eut* genes, a locus consisting of 19 genes in *E. faecalis* (Del Papa and Perego, 2008; Fox et al., 2009; Kaval and Garsin, 2018). The central enzyme in EA catabolism is the ethanolamine ammonia lyase consisting of the two subunits EutB and EutC. In the presence of the cofactor adenosylcobalamin (AdoCbl), EutB/C breaks down EA into acetaldehyde and ammonia, which serve as cellular supply for carbon and nitrogen, respectively (Kaval and Garsin, 2018). *E. faecalis* can grow on EA as sole carbon source, but only under anaerobic conditions. It is presumed that *E. faecalis* ferments EA, as no alternative electron acceptor was provided in the minimal medium (Garsin, 2010).

The *eut* gene expression is controlled by the EutV/W two-component system, which comprises the sensor histidine kinase EutW and the response regulator EutV. In the presence of EA, the histidine kinase EutW undergoes autophosphorylation and the phosphoryl group is transferred to a recipient domain on EutV (Del Papa and Perego, 2008; Fox et al., 2009). Phosphorylated EutV interacts with transcriptional terminators that precede certain *eut* open reading frames (ORFs). The binding of EutV prevents the formation of terminators and enables the RNA polymerase to generate full-length transcripts (Ramesh et al., 2012; DebRoy et al., 2014a). In addition to EA, *eut* gene expression also depends on the presence of Adenosylcobalamin (AdoCbl). AdoCbl binds to a riboswitch which is part of the small, trans-acting RNA EutX. This small RNA contains also a binding site that normally sequesters active EutV. Only in the presence of AdoCbl, a shorter form of EutX devoid of the EutV

binding site is generated, which leads to the transcriptional read through of multiple *eut* genes (DebRoy et al., 2014b).

It is important to note that the gastrointestinal tract is a rich source of EA, a component of the phospholipid phosphatidylethanolamine present in bacterial and eukaryotic cell membranes and in the host diet. The utilization of this compound could represent a colonization and fitness advantage for *E. faecalis* over other members of the microbiota, as it has already been demonstrated for enteric pathogens such as *S. Typhimurium* and enterohemorrhagic *E. coli* (EHEC) (Thiennimitr et al., 2011; Winter et al., 2013).

### **1.6 Major facilitator superfamily transporter of *E. faecalis***

Drug extrusion through multidrug efflux pumps serves as an important mechanism of clinically relevant bacterial resistance to antibiotics. In addition to antibiotic resistance, accumulating evidence suggests that efflux pumps also have physiological functions that enable bacterial survival in their ecological niche. They can confer resistance to host-derived molecules including bile, fatty acids and host-defence molecules and some bacterial efflux pumps have been shown to be important for the survival and persistence of bacteria in the host (Piddock, 2006; Sun et al., 2014).

Bacterial efflux pumps are classified into five families, with the major facilitator superfamily (MFS) being the clinically relevant one in Gram-positive bacteria. MFS is one of the largest and most diverse families of transport proteins. Individual MFS members show a high substrate specificity, yet the diversity of transported substrates is enormously (e.g. ions, simple sugars, oligosaccharides, inositols, drugs, amino acids, nucleosides, organophosphate esters, Krebs cycle metabolites) (Pao et al., 1998; Law et al., 2008).

The substrate of *E. faecalis* MFS transporter (OG1RF\_10079) has not been identified yet. The transporter shows sequence homology to NorA, a protein involved in the resistance of *Staphylococcus aureus* to norfloxacin, and is the most homologous gene to *hpt* from *L. monocytogenes*, a gene involved in virulence and fosfomycin resistance (Yamada et al., 1997; Scotti et al., 2006). However, Riboulet-Bisson et al. could show that *E. faecalis* MFS transporter is neither implicated in the resistance to these antibiotics nor in *E. faecalis* virulence in a mouse peritonitis model (Riboulet-Bisson et al., 2008).

Furthermore, they identified *E. faecalis* MFS as a member of the Ers regulon. The transcriptional regulator Ers is involved in bacterial survival against oxidative stress, virulence and the regulation of several metabolic pathways (Giard et al., 2006; Riboulet-Bisson et al., 2008). They suggested glycerol transport as a possible function of *E. faecalis* MFS transporter, because growth of a MFS mutant on

glycerol was slightly impaired. However, the weak phenotype indicates that glycerol is not the main substrate of this transporter (Riboulet-Bisson et al., 2009).

### 1.7 Aim of the study

Dysbiotic changes associated with IBD are characterized by an over-representation of opportunistic pathogens and a loss of beneficial organisms, indicating that the pathogenic potential of a dysbiotic community can be linked to certain organisms. Consequently, the specific contribution of individual bacteria to disease pathogenesis needs to be investigated in detail. We are using *E. faecalis*, a resident member of the intestinal microbiota at the interphase between commensal and pathogen, as model organism to study microbe-host interactions relevant for the development of chronic colitis in a genetically susceptible host.

Bacterial interactions have been implicated in the pathogenesis of IBD, but the influence of co-colonizing microbes on gene expression and colitogenic activity of an opportunistic pathogen is hardly investigated. For this purpose, we are investigating the transcriptional and functional activity of *E. faecalis* in two gnotobiotic experimental settings. First in a monoassociated system and second as part of a simplified microbial consortium (SIHUMI). *E. faecalis* disease-associated gene expression was addressed by RNA sequencing of bacteria isolated from healthy WT and inflamed IL-10<sup>-/-</sup> mice. We show that *E. faecalis* adapts transcriptionally to inflammatory conditions and, more remarkably, to co-colonizing bacteria. We targeted genes highly upregulated in response to inflammatory conditions to study their influence on *E. faecalis* survival and colitogenic activity, namely a major facilitator superfamily transporter (MFS) and genes of the ethanolamine utilization (eut) locus. Using *E. faecalis* deletion mutants, we were able to establish a novel correlation between *E. faecalis* ethanolamine utilization and a protective function in the context of experimental colitis.

To unravel the etiology of SIHUMI-induced colitis, we colonize WT and IL-10<sup>-/-</sup> mice with SIHUMI consortium in the presence and absence of the opportunistic pathogens *E. faecalis* or *E. coli*. We demonstrate that bacterial consortia interactions reprogram the colitogenic activity of opportunistic pathogens which indicates that the colitogenic function of a bacterial strain is not only defined its gene repertoire, but also by interaction with co-colonizing microbes.

### 3.2. Bacterial strains and cultivation

For this study, we used the characterized *E. faecalis* strain OG1RF. The *eut* VW double deletion mutant (Debroy et al., 2012) was kindly provided by Danielle Garsin (The University of Texas, Department of Microbiology and Molecular Genetics). The isogenic *mfs* deletion mutant was generated in this study (for details see 3.5). *E. faecalis* strains (Table 2) were cultivated in Brain Heart Infusion (BHI) broth or on BHI agar (BD Difco) at 37°C under aerobic conditions, unless otherwise indicated.

For *E. faecalis* growth experiments on EA, minimal medium M9HY was prepared as described previously (Del Papa and Perego, 2008). The M9HY medium was supplemented with glucose at 100mM or EA at 40 mM final concentration. Cyanocobalamin (Carl Roth) was used as exogenous vitamin B12 source. The M9HY medium was inoculated with the different *E. faecalis* strains from overnight (ON) cultures. Cells were washed twice in nitrogen-gased M9HY medium without carbon sources and grown at 37°C under anaerobic conditions in an anaerobic chamber (Whitley Hypoxystation H85, Meintrup DWS Laborgeräte GmbH) containing a H<sub>2</sub>/ N<sub>2</sub> gas mixture (10:90).

The SIHUMI (Eun et al., 2014) consortium (Table 2, members of the consortium are highlighted in red color) was kindly provided by Prof. Balfour R. Sartor (Division of Gastroenterology and Hepatology, University of North Carolina, Chapel Hill, USA). SIHUMI species were cultivated under anaerobic conditions on Wilkins-Chalgren-Agar (WCA, Thermo Fisher Scientific) in an anaerobic chamber or in hungate tubes (VWR International) containing WCA medium gassed with N<sub>2</sub> and supplemented with 0.05% (w/v) L-cystein (Carl Roth), 0.002% (w/v) dithiothreitol (DTT, Sigma Aldrich) and 0.0025% phenosafranin (Sigma Aldrich).

Bacterial cryo-stocks were prepared from ON cultures by mixing the bacterial suspension 1:1 with filter-sterilized glycerol in culture medium (40% v/v) in cryo-tubes before freezing and storage at -80°C. The purity of bacterial stocks was controlled by aerobic and anaerobic culture on agar plates and by sequencing of the 16S rRNA gene using primer 27F (5'-AGAGTTTGATCCTGGCTCAG-3') and 1492R (5'-GGTTACCTTGTTACGACTT-3'), as described previously (Lane, 1991; Klaring et al., 2013).

**Table 2.** Bacterial strains used in this study

### 3.3 Animal experiments – Ethical statement and housing

129S6/SvEv WT and IL-10<sup>-/-</sup> mice were used for monoassociation experiments and housed in isolators in the National Gnotobiotic Rodent Center, University of North Carolina, USA. All animal procedures were approved by the Institutional Animal Care and Use Committee, Harvard Medical School, and the University of North Carolina.

129S6/SvEv WT and IL-10<sup>-/-</sup> mice were used for SIHUMI colonization experiments and housed in isolators at the Core Facility Mikrobiom/Gnotobiologie of the Technical University Munich, ZIEL – Institute for Food & Health. All animal procedures were approved by the Committee on Animal Health and Care of the local government (Regierung von Oberbayern, AZ 55.2-1-54-2532-109-2015).

### 3.4 Animal experiments – Experimental design

Mice were fed a standard Chow diet (ssniff) ad libitum and were killed by CO<sub>2</sub>. Littermates were used when possible, or siblings from multiple breeders were combined and randomly assigned before assignment to experimental groups.

For monoassociation, germfree 129S6/SvEv WT and IL-10<sup>-/-</sup> mice were colonized at the age of 10–12 weeks with either *E. faecalis* WT OG1RF or  $\Delta$ eut VW mutant strain by oral and rectal swab. The mice were sacrificed after different periods of colonization (1, 4, 8, 16, 20, 24 weeks).

For colonization with the SIHUMI consortium, a bacterial mixture was prepared as follows. The bacteria were grown individually in hungate tubes for 24 h. A mixture of all strains with an equal cell density of  $1 \times 10^9$  cells/ml was prepared in sterile glass tubes, mixed 1:1 with sterile glycerol in culture medium (40% v/v, gassed with  $N_2$ ) and sealed with a rubber septum. The bacterial mixture was stored at  $-80^\circ\text{C}$  until use. Germfree 129S6/SvEv WT and  $IL-10^{-/-}$  mice were colonized at the age of 10 weeks with  $1 \times 10^8$  cells/species by repetitive oral gavage (1x week 0, 1x week 1). The composition of the bacterial consortium differed between the experimental groups as shown in Table 3. All mice were sacrificed 4 or 16 weeks after colonization.

**Table 3.** Composition of the bacterial consortium in the respective experimental groups

### 3.5 Generation of the *mfs* deletion mutant

An in-frame deletion of 81% of the *E. faecalis* OG1RF gene *mfs* (Locus Tag: OG1RF\_10079, GeneID: 12289265) was generated using a method described before (Thurlow et al., 2009) with the following modifications: The mutagenesis strategy (Figure 3) and relevant primers (Table 4) were designed by Luis Felipe Romero Saavedra (Dr. von Hauner Children's Hospital, Ludwig Maximilians University). Fragments up- and downstream (935 bp and 1060 bp) of the *mfs* open reading frame were amplified by PCR using primers 10079\_5, 10079\_22, 10079\_33 and 10079\_66. The PCR products were digested with HindIII (Thermo Fisher Scientific) and ligated using T4 DNA ligase (Thermo Fisher Scientific). The ligation product was reamplified using the primer 10079\_1 and 10079\_44 resulting in a 1942 bp PCR product, lacking 81 % of the *mfs* gene ( $\Delta$ mfs).

For all PCR reactions, a high-fidelity DNA polymerase (Phusion HS II, Thermo Fisher Scientific) was used following manufacturer's instructions. The PCR product was purified using the MSB® Spin PCRapace kit (Stratagene), digested with the restriction enzymes BamHI and NcoI (Thermo Fisher

Scientific) and ligated with the replication-thermosensitive vector pLT06 (Thurlow et al., 2009) previously digested with the same restriction enzymes.

Subsequently, the ligated products were electroporated into electro-competent *E. coli* XL-1 Blue (Agilent) for propagation and grown on LB agar plates containing 10 µg/ml chloramphenicol (Cm, Carl Roth), 20 µg/ml X-Gal (VWR) and 0.1 mM IPTG (Applichem) at 30°C under aerobic conditions. Blue colonies were isolated and screened for the presence of the  $\Delta mfs$  insert using pLT06\_fwd and pLT06\_rev primers.

Positive colonies were grown overnight (ON) in LB broth containing Cm at 30°C. The plasmid was purified using NucleoSpin Plasmid EasyPure kit (Macherey-Nagel) and sequenced using the primers 10079\_seq\_Fw and 10079\_seq\_Rv to verify the desired construct. Subsequently, the  $\Delta mfs$  deletion construct was transformed into electrocompetent *E. faecalis* OG1RF cells (chapter 3.6). After transformation, bacteria were grown for 1.5 h at 37°C and then transferred onto BHI plates containing 20 µg/ml Cm, 20 µg/ml X-Gal and 0.1 mM IPTG. After ON incubation at 30°C, blue colonies were screened for the presence of the pLT06/ $\Delta mfs$  construct by PCR using primers pLT06\_for and pLT06\_rev. Positive colonies were grown in BHI broth supplemented with 20 µg/ml Cm at 30 °C ON.

The liquid cultures were diluted 1:1000 in fresh BHI broth supplemented with Cm (pre-warmed to 44°C) and incubated ON at 44 °C, driving the integration of the construct into the bacterial chromosome by homologous recombination. Bacterial culture was then diluted and plated on BHI plates containing Cm, X-Gal and IPTG incubated ON at 44 °C. The integration was confirmed by PCR using primer 10079\_seq\_Fw in combination with 10079\_22 and 10079\_seq\_Rv with 10079\_33.

Positive isolates were grown in BHI media without antibiotic selection at 30 °C for 3 h followed by an immediate temperature switch to 44°C and ON incubation, thereby forcing the excision of the plasmid from the chromosome. The positive isolates were serially passaged in the same way for 3 times, followed by plating on BHI agar containing X-Gal and IPTG at 30 °C. The resulting white colonies indicate the absence of the plasmid and were screened for the loss of Cm resistance. The presence of the deletion was tested by PCR using primers 10079\_5 and 10079\_6. Positive clones were selected and isolated genomic DNA (chapter 3.8) was sent for sequencing with 10079\_seq\_Fw primer (GATC) to confirm the deletion of the *mfs* gene. The generated deletion mutant OG1RF  $\Delta mfs$  containing a 1005 bp deletion is listed in Table 2.

**Table 4.** Primers used for the generation of the  $\Delta mfs$  deletion mutant from *E. faecalis* OG1RF

Primer	Sequence	Restriction site

10079_1	AGGCGGATCCCATGACGACAGCCGATGAGC	BamHI (GGATCC)

**Figure 3: Mutagenesis strategy**

Mutagenesis strategy for the construction of the  $\Delta mfs$  deletion mutant from *E. faecalis* OG1RF. Different PCRs were performed to generate an 81% deletion of *E. faecalis mfs* gene. The binding sites of the relevant primers on the *E. faecalis* genome are shown in the upper part, the resulting deletion of the *mfs* gene is shown in the lower part of the figure.

### 3.6 Preparation of electrocompetent *E. faecalis* cells

*E. faecalis* OG1RF was inoculated in 10 ml BHI broth and grown at 37°C. The ON culture was diluted 1:20 with 100 ml fresh BHI broth and incubated at 37°C until an Optical Density (OD) at 600 nm between 0.5 and 1 was reached. The bacterial cells were chilled on ice for 20 min and harvested by

centrifugation at 3000 rpm for 10 min at 4°C. The cell pellet was resuspended in 2 ml sterile ddH<sub>2</sub>O and centrifuged at 13000 rpm for 1 min at 4°C.

Subsequently, the cell pellet was resuspended in 500 µl lysozyme solution (10 mM Tris pH 8.0, 20 % sucrose, 10 mM EDTA, 50 mM NaCl) containing freshly added mutanolysin (Sigma Aldrich) and lysozyme (Sigma Aldrich), at a final concentration of 2 µg/ml and 25 µg/ml, respectively. The bacterial suspension was incubated for 20 min at 37 °C with gentle shaking. Subsequently, bacteria were washed 3 times with 1 ml of electroporation buffer (10 mM Tris pH 8.0, 0.5 M sucrose, 10 % glycerol). Finally, cells were resuspended in 500 µl of electroporation buffer and divided into 50 µl aliquots. The generated electrocompetent *E. faecalis* cells were stored at -80 °C until use.

### 3.7 Preparation of bacterial lysates

Bacterial lysates were prepared as described previously (Eun et al., 2014). Briefly, individual bacterial colonies were inoculated under anaerobic conditions in 20 ml broth for 24 hours. The bacterial cultures were washed twice with and resuspended in sterile PBS. Per 1 ml bacterial suspension, 250 µl freshly prepared MD solution (0.1 M MgCl<sub>2</sub>, 100 µg/ml DNaseI) was added. Bacteria were disrupted using a FastPrep®-24 (MP Biomedicals) and the suspension was sterilized using a 0.2 µm syringe filter. The protein concentration was determined by using the Roti®-Nanoquant Bradford assay (Carl Roth). The lysates were stored at -80°C until use.

### 3.8 Bacterial DNA extraction

Bacterial cells or intestinal contents were resuspended in 600 µl stool stabilizer (Stratech), mixed with 400 µl phenol/chloroform/iso-amyl alcohol (Carl Roth) and lysed by mechanical lysis using a FastPrep®-24 (MP Biomedicals). The homogenized mixture was incubated for 8 min at 95°C and DNA was isolated by phase separation via centrifugation at 16000 g for 5 min at 4°C. Contaminating RNA was digested with 0.1 µg/µl RNase A (VWR) for 30 min at 37°C. Subsequently, DNA was purified using the gDNA clean-up kit (Macherey-Nagel) according to the manufacturer's instructions. DNA concentration and purity were analyzed with a NanoDrop® 1000 spectrophotometer (Thermo Fisher Scientific).

### 3.9 Bacterial community analysis via quantitative real-time PCR (qPCR) assay

For bacterial community analysis, oligonucleotide primers were used to target species-specific regions of the 16S ribosomal RNA gene. Quantification was performed using the LightCycler 480 Universal Probe Library System (UPL, Roche) with the following 2-step program: 95°C for 3 min, 40 cycles of 95°C for 5 sec and 60°C for 10 sec. Reactions were carried out in 10 µl volumes containing

1x PCR master mix (Brilliant III, Agilent), 200 nM of each primer, 100 nM of probe and 1 ng of DNA template. Primers (Sigma Aldrich) and corresponding probes (Roche) are listed in Table 5. Positive and negative controls were included in every run. The specificity of primer pairs was validated by using an equal mixture of DNA from all SIHUMI species spiked with increasing concentrations of target species DNA. The Ct-value was only affected by changes in DNA concentration of the target species while not being affected by non-target DNA. Standard curves were generated for each species and used to enumerate the 16S gene copy numbers per species in intestinal content. 16S gene copy number per ng DNA was calculated via the molecular weight of the genome and 16S copy numbers/genome. The relative abundance of each species in intestinal content was calculated as previously described (Eun et al., 2014) using the following formula: [(copies of 16S rRNA gene for a specific SIHUMI bacterium/cumulative copies of 16S rRNA gene of all bacteria) × 100].

**Table 5.** Species specific 16S-targeted primers and UPL probes used for bacterial community analysis

### 3.10 Droplet Digital PCR

Droplet digital PCR (ddPCR™, Bio-rad) was performed at the Technical University Munich Campus in Straubing with the generous help of Dr. Josef Sperl (Chair: Chemie Biogener Rohstoffe). Therefore, DNA isolated from pure bacterial culture or colonic content of germfree or SIHUMI colonized mice was digested with BamHI-HF restriction enzyme (New England Biolabs) for 1 h to improve amplicon accessibility. The following DNA amounts were used for ddPCR reactions:

- DNA isolated from colon content: 50 ng
- DNA isolated from pure culture for standard curve generation: 50 ng, 5 ng, 0.5 ng, 0.05 ng, 5 pg, 0.5 pg, 0.05 pg

The ddPCR mixture contained 10 µl of 2x ddPCR™ Supermix for Probes (Bio-Rad), 900 nM of both forward and reverse primers and 125 nM of the respective UPL probe (Roche) in a total reaction volume of 20 µl. Primers and probes are listed in Table 5. The 20 µl reaction and 70 µl/reaction Droplet Generation Oil for Probes (Bio-Rad) were loaded into a droplet cartridge (Bio-Rad). After droplet generation, the emulsion was transferred into a 96 well plate and PCR was performed in a C-1000 thermal cycler (Bio-Rad) with following conditions: 95°C for 10 min, 40 cycles of 94°C for 30 sec and 60°C for 1 min. PCR-positive and PCR-negative droplets were detected using a Bio-Rad droplet reader. The Quantasoft software was used for downstream analysis.

### 3.11 Bacterial RNA isolation

Bacterial total RNA was isolated as described previously (Ridaaura et al., 2013). Briefly, bacterial cells were mechanically disrupted using a FastPrep®-24 bead beater (MP Biomedicals). RNA was isolated by phenol:chloroform:iso-amyl alcohol (25:24:1, pH 4.5, Carl Roth) extraction, precipitated with isopropanol and purified using the NucleoSpin® RNA extraction kit (Macherey-Nagel). RNA concentration and purity was analyzed using a NanoDrop® 1000 spectrophotometer (Thermo Fisher Scientific). The RNA integrity was assessed by Gel Electrophoresis. Contaminating genomic DNA was digested using TURBO DNase (Thermo Fisher Scientific) according to the manufacturer's instructions.

### 3.12 Reverse transcription and gene expression analysis via qPCR (bacteria)

Complementary DNA (cDNA) was synthesized from 500 ng RNA using the Moloney murine leukemia virus (MMLV) Point Mutant Synthesis System (Promega) and random hexamers. The absence of contaminating gDNA was ensured for each sample by negative controls, whereby no reverse transcriptase was added to the reaction. Quantification was performed by using the LightCycler 480 Universal Probe Library System (UPL, Roche) with the following 2-step program: 95°C for 3 min, 40

cycles of 95°C for 5 s and 60°C for 10 sec. The reactions were carried out in 10 µl volumes containing 1x PCR master mix (Agilent), 400 nM of each primer, 200 nM of probe and 1 µl of cDNA template. Primers (Sigma Aldrich) and corresponding UPL probes (Roche) are listed in Table 6. Relative quantification of gene expression was calculated by means of  $2^{-\Delta\Delta C_t}$  values:  $2^{-[(C_{t\text{target gene}} - C_{t\text{housekeeping gene}})_{\text{treated}} - (C_{t\text{target gene}} - C_{t\text{housekeeping gene}})_{\text{untreated}}]}$ . The values were normalized to the *E. coli* LF82 housekeeping genes *cysG*, *pyrA* and *rpoA*.

### 3.13 Immunomagnetic separation of *E. faecalis* cells from the intestinal content

The isolation method was modified after Nolle (2017) (Nolle, 2017 ). Frozen colonic content from SIHUMI colonized mice was disrupted by bead beating in 1 ml RNAlater (Sigma Aldrich) using glass beads (1 mm, Carl Roth). Subsequently, samples were diluted with wash buffer (PBS, 0.5% biotin-free BSA, 10% RNAlater) and filtered through 3 cell strainers with decreasing pore size (VWR, 100 µm/70 µm/30 µm).

The samples were kept on ice throughout the protocol and only pre-chilled buffer solutions were used. The bacterial cells were pelleted by centrifugation at 5000 g for 5 min at 4°C and resuspended in 1 ml wash buffer. The samples were mixed with 10 µl *Enterococcus* specific antibody (biotinylated, Thermo Fisher Scientific PA1-73123) and incubated for 10 min at 4°C with gentle agitation. The specificity of the anti-*Enterococcus* antibody was tested by western blot analysis (chapter 3.19.2).

The ideal antibody concentration was determined by spiking of intestinal content from germfree mice with *E. faecalis*, *E. coli* and *L. plantarum* in different mixing ratios followed by immunomagnetic separation (IMS) with distinct antibody concentrations. *E. faecalis* cell number in relation to other bacterial species was determined by plating and CFU determination before and after IMS. The samples were centrifuged for 2 min at 9600 g. After a washing step, the cells were resuspended in 100 µl wash buffer and 10 µl Streptavidin MicroBeads (Miltenyi Biotec) were added per sample. After incubation for 15 min at 4°C with gentle agitation, the cells were washed with wash buffer and resuspended in 500 µl separation buffer (PBS, 0.5% biotin-free BSA, 2 mM EDTA, 10% RNAlater). Magnetically labeled *E. faecalis* cells were isolated using MACS filter columns (LS, Miltenyi Biotec) in a MidiMACS™ Separator (Miltenyi Biotec) according to the manufacturer's instructions and total bacterial RNA was isolated.

### 3.14 Microbial RNA sequencing (RNA seq)

#### 3.14.1 RNA seq of *E. faecalis* isolated from monoassociated mice

Bacterial RNA prepared from the colonic content of *E. faecalis* OG1RF monoassociated WT and IL-10<sup>-/-</sup> mice (n=8 mice/group; colonization period: 16 weeks) was sequenced as described previously (Ocvirk et al., 2015). RNA isolation and rRNA depletion was done by Jonathan Hansen and Sandrine Tchaptchet from the Division of Gastroenterology and Hepatology of the University of North Carolina in Chapel Hill. Library preparation and sequencing was performed at the Washington University St. Louis Genome Technology Access Center generating in total 190 million unidirectional 50 bp reads using an Illumina HiSeq2000 instrument (Illumina).

### 3.14.2 RNA seq of *E. faecalis* isolated from SIHUMI colonized mice

*E. faecalis* cells in the colonic content of SIHUMI colonized Wt (n=6 mice/group; colonization period: 16 weeks) and IL-10<sup>-/-</sup> mice (n=13 mice/group; colonization period: 16 weeks) were isolated by IMS. Total bacterial RNA was isolated as described above (chapter 3.11) and purified using the RNeasy® MinElute™ Cleanup kit (Qiagen). Contaminating gDNA was eliminated using TURBO DNase (Thermo Fisher Scientific) and RNA integrity was validated by agarose gel electrophoresis.

Ribosomal RNA was depleted by using the RiboMinus™ Transcriptome Isolation Kit (Bacteria, Thermo Fisher Scientific) according to the manufacturer's instructions. Subsequently, the RNA was fragmented for 180 sec using a Covaris E220 sonicator set at 10% duty cycle, intensity of 5 and 200 cycles/burst in 120 µl 1 mM Tris-EDTA pH 8. The fragmented RNA was precipitated with 1 µl glycogen (Thermo Fisher Scientific), 1:10 sample volume 3 M sodium acetate (Ambion) and 2.5 sample volume of 100% EtOH.

Next, RNA was dephosphorylated using 10 U per 300 ng RNA Antarctic phosphatase at 37 °C for 30 min (New England Biolabs). The RNA fragments were recovered using the miRNeasy® Mini kit (Qiagen) followed by 5' phosphorylation using 20 U T4 polynucleotide kinase at 37°C for 60 min (Thermo Fisher Scientific). Again, the miRNeasy® Mini kit was used for recovery. RNA fragment size was examined using the BioAnalyzer on an RNA Pico Chip (Agilent Technologies).

The cDNA library was prepared as described in the TruSeq® Small RNA Library Prep Reference Guide (Illumina) with the following exception. After adapter ligation and reverse transcription, fragments were size selected between 145 bp and 300 bp corresponding to an insert length between 18 bp and 173 bp. The sequencing was conducted at the Core Facility Microbiome/NGS (ZIEL – Institute for Food & Health, Technical University of Munich), generating in total 300 million unidirectional 50 bp reads using an Illumina HiSeq2000 instrument.

### 3.14.3 Bioinformatics

Data analysis was performed using tools implemented in the Galaxy web platform (Afgan et al., 2018) (server: usegalaxy.eu). Quality of the raw sequence data was assessed with the FastQC tool (version 0.71). After adapter clipping with the Clip adapter sequences tool (version 1.0.3), Illumina FASTQ files were mapped to the reference genome of *E. faecalis* OG1RF (GenBank: NC\_017316.1) using Bowtie2 (version 2.3.4.2). Using htseq-count, the aligned reads overlapping with genomic features were counted. Differentially expressed genes between bacteria isolated from inflamed IL-10<sup>-/-</sup> versus healthy WT mice were determined using DEseq2 (version 2.11.40.2). KEGG gene set enrichment

analysis was executed using the Bioconductor clusterProfiler package (version 3.8.1) implemented in R (Yu et al., 2012).

### 3.15 Cytokine quantification

IFN $\gamma$ , TNF, IL-12p40, IL-6 and IL-17A concentration in cell culture supernatant was quantified using commercially available ELISA kits (eBioscience). Serum amyloid A (SAA) concentration in murine plasma was determined using a commercially available ELISA kit from Immunology Consultants Laboratory (ICL).

### 3.16 Histological analysis

#### 3.16.1 Tissue processing

The intestinal tract of gnotobiotic WT and IL-10<sup>-/-</sup> mice was removed immediately after killing and cleaned from stool. Cross-sections or “swiss-roles” (Moolenbeek and Ruitenbergh, 1981) of parts of the intestinal tract were fixed in 10% phosphate buffered formaldehyde (VWR) or Carnoy’s solution (60% dry Methanol, 30% Chloroform, 10% glacial acetic acid), dehydrated (Leica TP1020, Table 7) and embedded in paraffin (Paramat extra, VWR) by using a Leica EG1150 embedding station .

**Table 7.** Dehydration and paraffin embedding of fixed tissue sections

Step	Reagent	Time
1	70% EtOH	60 min
2	70% EtOH	60 min
3	80% EtOH	60 min
4	96% EtOH	60 min
5	96% EtOH	60 min
6	100% EtOH	60 min
7	100% EtOH	60 min
8	100% EtOH	60 min
9	Xylene	60 min
10	Xylene	60 min
11	Paraffin	60 min
12	Paraffin	60 min

### 3.16.2 H&E staining and histological analysis

For histological analysis, fixed paraffin embedded tissue samples were cut into 5 µm sections using a Leica rotary microtome RM2255, mounted on SuperFrost® microscope slides (VWR) and dried overnight. The tissue sections were deparaffinized, rehydrated and stained with hematoxylin and eosin (MEDITE) in an automated manner using the multistainer station LeicaST5020 (Table 8). The slides were mounted with Roti®-Histokitt (Carl Roth) and covered with a glass slide (VWR). The histopathology was evaluated by an independent examiner in a blinded manner as described previously (Katakura et al., 2005), resulting in a score from 0 (not inflamed) to 12 (highly inflamed).

**Table 8.** Deparaffinization, rehydration and H&E staining of tissue sections (LeicaST5020)

Deparaffinization and Rehydration			H&E staining		
Step	Reagent	Time	Step	Reagent	Time
1	Xylene	3 min	6	dH <sub>2</sub> O	1 min
2	Xylene	3 min	7	Hematoxylin	2 min
3	100% EtOH	2 min	8	dH <sub>2</sub> O	2 min
4	96% EtOH	2 min	9	Eosin	2 min
5	70% EtOH	1 min	10	70% EtOH	1 min
			11	96% EtOH	1 min
			12	100% EtOH	1 min
			13	100% EtOH	1.5 min
			14	Xylene/EtOH	1.5 min
			15	Xylene	2 min
			16	Xylene	2 min

### 3.17 RNA isolation, reverse transcription and gene expression analysis (mouse)

#### 3.17.1 RNA isolation

Tissue sections of distal colon were stored in RNAlater (Sigma Aldrich) at -80°C. Tissue samples were transferred into 500 µl RA1 buffer (Macherey Nagel) supplemented with 10 mM DTT (Sigma Aldrich) and the tissue was homogenized using a Micra D-1 homogenizer. RNA was isolated using the NucleoSpin® RNA Kit (Macherey Nagel) according to the manufacturer's instructions. The quantity and purity of the isolated RNA was measured with a NanoDrop® ND-1000 spectrophotometer (Thermo Fisher Scientific).

### 3.17.2 Reverse transcription and gene expression analysis via qPCR

Reverse transcription and gene expression analysis was performed as described for bacterial RNA (chapter 3.12) with following exceptions. cDNA was synthesized from 1000 ng RNA. Relative gene expression values were normalized to GAPDH and HPRT expression. Primers (Sigma Aldrich) and corresponding probes (Roche) are listed in Table 9.

**Table 9.** Primers and corresponding UPL probes used for mouse gene expression analysis

Targeted gene	Gene ID (NCBI gene)	Oligonucleotide sequence (5'-3')	UPL probe
<b>GAPDH</b>	14433	L: GGGTTCCTATAAATACGGACTGC R: CCATTTTGTCTACGGGACGA	52

### 3.18 Mesenteric lymph node cell cultures

Mesenteric lymph nodes (MLN) were aseptically harvested from gnotobiotic WT and IL-10<sup>-/-</sup> mice. The tissue was homogenized and filtrated through 70  $\mu$ m cell strainers (VWR) resulting in unfractionated single cell suspensions. MLN cells (5x10<sup>5</sup> cells per well), isolated from individual mice (for IL-10<sup>-/-</sup> mice) or a pool of mice (for WT mice), were cultured in RPMI-1640 medium (Sigma Aldrich) containing 10% fetal calf serum (Biochrom) and 1% antibiotics/antimycotics (Sigma Aldrich). Cells were stimulated for 72 hours with corresponding bacterial lysates (15  $\mu$ g/ml) from the strain/species that was used for colonization. The supernatants were collected for cytokine analysis, as indicated in 3.15.

### 3.19 SDS-PAGE and immunoblotting

#### 3.19.1 Mouse serum IgG or IgA against bacterial lysates

Bacterial lysates were prepared as described in 3.7, mixed with TruPAGE 4x LDS buffer (Sigma Aldrich) and denatured for 10 min at 70°C. The lysates were subjected in a concentration of 3 µg/lane to discontinuous denaturing polyacrylamid gel electrophoresis (SDS-PAGE), transferred onto a polyvinylidene difluoride membrane (PVDF, GE Healthcare Amersham) and blocked at RT for 1 h in 5% skim milk-TBST (0.05% Tween in TBS). After over-night incubation with a 1:500 dilution of mouse serum (pool of serum from 6 WT or 10 IL-10<sup>-/-</sup> mice) in 5% skim milk-TBST, the membrane was washed 3 times in TBST and incubated with either a 1:2500 dilution of goat anti mouse immunoglobulin G (IgG) alkaline phosphatase conjugate (Sigma Aldrich) or a 1:1000 dilution of goat anti mouse immunoglobulin A (IgA) FITC conjugate (Invitrogen) for 2 h. Subsequently, the membrane was washed 3 times with TBST and antibody binding was detected using nitro-blue tetrazolium (NBT) /5-bromo-4-chloro-3'-indolylphosphate (BCIP) tablets (Roche) for IgG or by using a Typhoon Trio+ imager (GE Healthcare Amersham) for IgA.

#### 3.19.2 Specificity testing of *Enterococcus* antibody

The specificity of *Enterococcus* polyclonal antibody (Biotin coupled, Thermo Fisher Scientific) was confirmed via western blot analysis as described in 3.19.1 with following changes. After SDS-PAGE and transfer, the membranes were incubated with the polyclonal rabbit antibody raised against *Enterococcus* whole cells (*Enterococcus faecium*) in a dilution of 1:2000 in 5% skim milk-TBST ON at 4°C. After washing in TBST and incubation for 1 h at RT with a streptavidin-peroxidase polymer (Sigma Aldrich) diluted 1:2000 in 5% dry skim milk-TBST, the membrane was washed again 3 times with TBST, incubated with ECL-Prime (GE Healthcare Amersham) for 5 min and exposed to X-ray film (Bender).

### 3.20 Ethanolamine quantitation in colonic content by LC-MS/MS analysis

Quantitation of ethanolamine in colonic content from WT and IL10<sup>-/-</sup> mice monoassociated with *E faecalis* OG1RF or  $\Delta$ eut VW was performed at the Bavarian Center for Biomolecular Mass Spectrometry (BayBioMS). Sample preparation and mass spectrometry quantitation was modified after Bertin et al (Bertin et al., 2011). Briefly, colonic content was diluted 1:20 with purified ddH<sub>2</sub>O (Millipore) and debris was removed by two centrifugation steps at 4°C (2000 g for 20 min, 6000 g for 5 min).

1 ml of colonic content was spiked with 65 µL of a 1 mg/ml solution of ethanol-1,1,2,2-d<sub>4</sub>-amine (Sigma Aldrich) as internal standard. For protein removal, 1 ml supernatant was incubated with 100

μl 40% sulfosalicylic acid (Sigma Aldrich) followed by centrifugation at 11000 g for 15 min. Precipitated proteins were removed and ethanolamine (EA) was derivatized with dansyl chloride (Sigma Aldrich) for mass spectrometry quantitation. For derivatization, supernatants were mixed with 300 μl of 0.5 M NaHCO<sub>3</sub> (Merck), 2 ml of 10 mg/ml dansyl chloride in acetone (Sigma Aldrich) and 200 μl of 1 M NaOH (Sigma Aldrich).

The samples were incubated for 20 min at RT in the dark and residual dansyl chloride was removed by addition of 200 μl 25% NH<sub>4</sub>OH (Sigma Aldrich). Subsequently, the sample volume was adjusted to 5 ml with acetonitrile (Sigma Aldrich) and 10 μl of the solution was injected for LC-MS/MS analysis. The LC-MS/MS system consisted of a Shimadzu-Prominence LC system, including a LC-20AD pump, a DGU-20A3 degasser, a SIL-20A autosampler and a CTO-20A column oven, with a QTRAP® 4000 mass spectrometer equipped with an Turbo V ion source (Applied Biosystems).

Analyst® software (Applied Biosystems, version 1.6.2) was used for instrument control, data acquisition and data processing. Chromatographic separation was performed on a Kinetex 5u XB-C18 100 A column (100 x 2.1 mm, 5 μm, Phenomenex) using water/formic acid (100/0.1 v/v) as solvent A and acetonitrile/formic acid (100/0.1, v/v) as solvent B at a flow rate of 400 μl/min and a column temperature of 40°C. Starting with 5% solvent B, the amount of B in the mobile phase was increased to 100% in 3 min and hold for 2 min, followed by re-equilibration at starting conditions for 3 min. The mass spectrometer was operated at 450°C in the positive electrospray ionization mode with the ion spray voltage set at 5500 V. Dansyl-ethanolamine was detected with MRM mode using the following settings: *m/z* 295.1/157 (entrance potential (EP) 10, declustering potential (DP) 70, collision energy (CE) 37, cell exit potential (CXP) 7, quantifier), 295.1/170 (EP 10, DP 72, CE 31, CXP 8, qualifier) and dansylethanol-1,1,2,2-*d*<sub>4</sub>-amine was used as internal standard: *m/z* 299.1/158 (EP10, DP 70, CE 37, CXP 7).

### 3.21 Statistical analysis

Statistical analyses were performed using Prism version 6.05 (GraphPad). Unless otherwise stated, data are presented as mean ± standard deviation. Statistical significant differences were determined using one- or two-way ANOVA followed by pair wise comparison testing (Tukey). Differences were considered significant for \**p*<0.05, \*\**p*<0.01, \*\*\**p*<0.001, \*\*\*\**p*<0.0001.

Analysis of RNAseq data was performed using Galaxy platform web platform (Afgan et al., 2018) or R as described in detail above.

## 4. RESULTS

### 4.1 Kinetic of *E. faecalis*-induced colitis in monoassociated IL-10<sup>-/-</sup> mice

To analyse the kinetics of *E. faecalis*-driven inflammation, we monoassociated germ-free WT and IL-10<sup>-/-</sup> mice at the age of 10 weeks with *E. faecalis* WT OG1RF for different periods of time. After 4, 8 and 12 weeks of colonization, IL-10<sup>-/-</sup> mice showed mild signs of inflammation in the distal colon as indicated by the histological score. Between the 12<sup>th</sup> and the 20<sup>th</sup> week of colonization, IL-10<sup>-/-</sup> mice started to develop severe distal colonic inflammation reaching a plateau after week 20 (Figure 4).

A similar disease pattern was also observed in mid colon with an overall lower level of inflammation (Figure 4B). In proximal colon, the inflammation persisted at a very low level throughout the analysed colonization periods (Figure 4C). All WT mice remained disease-free (Figure 4A-C). The colonization density as detected by countable colony forming units (CFU) in luminal colon contents was not affected by the level of inflammation (Figure 4D).

Figure 4: *E. faecalis* induces colitis in IL-10<sup>-/-</sup> mice between 12 and 20 weeks of colonization.

WT and IL-10<sup>-/-</sup> mice were monoassociated with *E. faecalis* for 4, 8, 12 and 24 weeks (w). (A) Histological inflammation score in the distal, (B) mid and (C) proximal colon. (D) *E. faecalis* counts/mg in luminal contents from colon.

The body weight increased with the age of the mice, but was not influenced by the degree of colonic inflammation (Figure 5). Cecum weight was generally slightly reduced in IL-10<sup>-/-</sup> compared to WT mice, but significance was only reached at a colonization time of 8 weeks (Figure 5B). Compared to WT mice, the weights of spleen and mesenteric lymph nodes (MLN) of IL-10<sup>-/-</sup> mice were significantly increased after a colonization period of 20 weeks and 8 weeks, respectively (Figure 5C and D).

Based on the kinetic of distal colonic inflammation and previous publications, 16 weeks of colonization were used in subsequent experiments. At this time, inflammation was still in the ascending phase and is therefore advantageous for the analysis of factors modulating disease severity.

**Figure 5: Spleen and MLN weights increase with the degree of intestinal inflammation.**

WT and IL-10<sup>-/-</sup> mice were monoassociated with *E. faecalis* for 4, 8, 12 and 24 weeks (w). (A) Body weight, (B) Cecum weight, (C) Spleen weight and (D) MLN weight.

## 4.2 *E. faecalis* adapts transcriptionally to a chronic inflammatory environment

We hypothesized that *E. faecalis* quickly adapts to a chronic inflammatory environment by altering its gene expression profile. These adaptation mechanisms are likely to be responsible for the persistence and virulence of these bacteria in a susceptible host. To assess *E. faecalis* disease-associated transcriptome, we monoassociated mice with *E. faecalis* OG1RF for 16 weeks and performed RNA sequencing of bacteria isolated from luminal colon content of healthy WT and inflamed IL-10<sup>-/-</sup> mice.

Transcriptional profiling identified 408 significantly up-regulated and 486 significantly down-regulated genes under conditions of chronic inflammation (Figure 6A and Figure S1A, Table S1). The samples clearly clustered according to mouse genotype as detected by principal component analysis (PCA), indicating that inflammation modulates *E. faecalis* gene expression (Figure S1B).

*E. faecalis* response to inflammation was characterized by an up-regulation of genes associated with bacterial stress response to unfavourable growth conditions. KEGG pathway enrichment analysis showed an enrichment of the biosynthesis of amino acids, quorum sensing, mismatch repair and oxidative phosphorylation among up-regulated genes (Figure 6B). Induction of these processes has also been observed in previous studies analyzing *E. faecalis* and *E. coli* adaptation during periods of stress (van de Guchte et al., 2002; Durfee et al., 2008; Ran et al., 2015).

Nucleotide synthesis genes in general down regulated, as indicated by an enrichment of purine and pyrimidine metabolism transcripts in wild type mice. Furthermore, a large number of genes involved in metabolism and nutrient acquisition were differentially expressed. Sugar metabolism and transport were repressed with an enrichment of starch and sucrose metabolism, ABC transport, PTS transport and glycolysis among down-regulated genes. On the other hand, genes necessary for the utilization of alternative carbon sources were up regulated with an enrichment of inositol phosphate metabolism, glycerolipid metabolism and ethanolamine utilization genes (Figure 6B and C).

**Figure 6: *E. faecalis* adapts transcriptionally to chronic colitis in monoassociated IL-10<sup>-/-</sup> mice.**

**(A)** Experimental setup: Transcriptional profiling of luminal bacteria isolated from the colon of monoassociated IL-10<sup>-/-</sup> (inflamed) and healthy WT mice (n=8/group) revealed 408 significantly up-regulated genes and 486 down-regulated genes in *E. faecalis* under inflammatory conditions. **(B+C)** Expression profiles of *E. faecalis* in an inflamed (IL-10<sup>-/-</sup>) vs. a non-inflamed (WT) environment in monoassociated mice **(B)** Expression distribution (log2 lower or higher) of genes for GSEA enriched categories (KEGG). The gene group containing *eut*-genes is highlighted red **(C)** Top 20 up-regulated genes. Only annotated genes with known function are shown. Genes of the *eut* locus and major facilitator transporter (OG1RF\_10079) are highlighted red. Gene functions were assigned according to KEGG database.

### 4.3 Bacterial genes highly up-regulated in inflamed mice do not affect the colonization and colitogenic activity of *E. faecalis* in a monoassociated system

Among the top up-regulated genes in inflamed IL-10<sup>-/-</sup> mice, 14 genes of the ethanolamine utilization (*eut*) locus and a major facilitator superfamily transporter (*mfs*) were identified (Figure 6C and Figure 7A). Up regulation in response to inflammation suggests important functions of these genes in the inflamed intestine. We hypothesized that the deletion of *eut* genes or *mfs* gene from *E. faecalis* may reduce bacterial survival and virulence under inflammatory conditions, leading to attenuated intestinal inflammation in monoassociated IL-10<sup>-/-</sup> mice (Figure 7B and C).

**Figure 7: *E. faecalis* *eut* operon and *mfs* gene are highly up-regulated in inflamed IL-10<sup>-/-</sup> mice.**

**(A)** Differential expression of genes in relation to a chronically inflamed environment is shown for significantly regulated *eut* genes and *mfs* gene. The log<sub>2</sub> ratio of mean abundance (IL-10<sup>-/-</sup> vs. WT) of normalized expression levels is shown (up regulation is indicated red, down regulation is indicated blue). **(B)** Experimental setup. Germfree WT and IL-10<sup>-/-</sup> mice were monoassociated with *E. faecalis* WT or  $\Delta$ *eut* mutant strain for 1 and 16 weeks. **(C)** Experimental setup. Germfree WT and IL-10<sup>-/-</sup> mice were monoassociated with *E. faecalis* WT or  $\Delta$ *mfs* mutant strain for 16 weeks

#### 4.3.1 Ethanolamine utilization

To determine whether the utilization of ethanolamine (EA) is relevant for *E. faecalis* colonization and colitogenic activity, we monoassociated germ-free WT and IL-10<sup>-/-</sup> mice with *E. faecalis* WT OG1RF or an  $\Delta$ *eut* mutant strain ( $\Delta$ *eut*) for 1 week to analyze early colonization effects or 16 weeks to analyze disease progression (Figure 7B). The  $\Delta$ *eut* strain does not express the *eut* genes and is not able to utilize EA (Fox et al., 2009; Debroy et al., 2012; Ramesh et al., 2012). *E. faecalis* OG1RF can utilize EA as sole carbon source under anaerobic growth conditions, while  $\Delta$ *eut* mutant strain is not able to grow on minimal medium supplemented with EA (Figure 8) (Del Papa and Perego, 2008).

**Figure 8: *E. faecalis* Δ*eut* mutant is not able to utilize EA as carbon source.**

*E. faecalis* OG1RF and Δ*eut* mutant were grown in M9HY minimal medium supplemented with glucose (+Gluc) or EA and vitamin B12 (+EA +B12) under anaerobic conditions and bacterial density was measured using OD<sub>600</sub>.

After 1 week of colonization, WT and IL-10<sup>-/-</sup> mice showed no signs of inflammation. After 16 weeks of colonization, IL-10<sup>-/-</sup> mice developed severe inflammation in the distal colon, independent of the *E. faecalis* strain used for monoassociation (OG1RF histopathological score: 5.0 ± 0.9, Δ*eut* histopathological score: 4.6 ± 0.5). All WT mice remained disease-free (Figure 9A and B).

*E. faecalis* OG1RF and Δ*eut* mutant strains showed a similar colonization density as detected by CFU in luminal contents from colon (Figure 9C). The colon inflammation in IL-10<sup>-/-</sup> mice was accompanied by elevated spleen weights (Figure 9D) and increased expression of pro-inflammatory markers in the distal colon tissue. The expression levels of TNFα, IL-12p40 and IL-17 were similar for both colonization groups, only IFNγ expression levels were increased in *E. faecalis* WT OG1RF compared to Δ*eut* mutant monoassociated IL-10<sup>-/-</sup> mice (Figure 9E).

**Figure 9: Ethanolamine utilization has no influence on the colitogenic activity and colonization density of *E. faecalis* in monoassociated IL-10<sup>-/-</sup> mice.**

Germ-free WT and IL-10<sup>-/-</sup> mice were monoassociated with *E. faecalis* WT or  $\Delta\text{eut}$  mutant strain for 1 and 16 weeks, respectively. **(A)** Histological inflammation in the distal colon. **(B)** Representative hematoxylin/eosin-stained sections of distal colon after 16 weeks of colonization. **(C)** *E. faecalis* presence in luminal contents from colon as log CFU counts/mg. **(D)** Spleen weights. **(E)** Cytokine expression in colon tissue sections. Values are shown as fold-change normalized to cytokine

expression levels in WT mice colonized with *E. faecalis* WT strain. **(F)** Quantitation of ethanolamine in luminal contents from colon.

To determine whether *E. faecalis* catabolizes EA *in vivo*, we measured EA concentrations in the intestinal fluid. Luminal EA concentrations were significantly higher in WT mice monoassociated with  $\Delta$ *eut* mutant, indicating catabolism of EA by *E. faecalis* OG1RF. This trend was also observed in IL-10<sup>-/-</sup> mice after 4 weeks of colonization, but after 16 weeks of colonization intestinal EA concentrations were similar in both *E. faecalis* OG1RF and  $\Delta$ *eut*-mutant monoassociated mice (Figure 9F).

Antigen-specific T cell responses were addressed *ex vivo*. MLN cells were isolated from IL-10<sup>-/-</sup> and WT mice monoassociated with *E. faecalis* OG1RF or  $\Delta$ *eut* mutant strain and re-activated with lysates of the corresponding *E. faecalis* strain. Already after 1 week of colonization, re-activated MLN cells from IL-10<sup>-/-</sup> mice secreted high amounts of IL-12p40 in response to *E. faecalis* lysate stimulation (Figure 10A). MLN cells isolated from WT mice also responded to stimulation with *E. faecalis* lysate by secretion of IL-12p40, but to a lesser extent than MLN cells from IL-10<sup>-/-</sup> mice (Figure 10A and B). Interestingly, IL-12p40 secretion from re-activated MLN cells was decreased in IL-10<sup>-/-</sup> mice colonized with  $\Delta$ *eut* mutant strain, suggesting an attenuated MLN immune response to  $\Delta$ *eut* mutant strain (Figure 10B). However, this difference in immune activation was independent of colonic pathology (Figure 9A).

**Taken together, deletion of ethanolamine utilization revealed no impact on *E. faecalis* colitogenic activity and survival in monoassociated mice.**

**Figure 10: IL-12p40 secretion of re-activated MLN cells is decreased for *E. faecalis*  $\Delta$ *eut* mutant.**

**(A)** IL-12p40 secretion of MLN cells isolated from *E. faecalis* OG1RF or  $\Delta eut$  mutant colonized IL10<sup>-/-</sup> and WT mice after 1 week and **(B)** 16 weeks of colonization that were re-activated with the corresponding bacterial lysate for 72 hours.

### 4.3.2 Major facilitator superfamily transporter

In order to test the hypothesis that the MFS transporter is important for the colonization and colitogenic activity of *E. faecalis* under inflammatory conditions, we constructed a mutant strain of *E. faecalis* OG1RF lacking *mfs* ( $\Delta mfs$ ) and confirmed the absence of *mfs* expression in *E. faecalis*  $\Delta mfs$  using real-time PCR (Figure 11A).

To ensure that the absence of *mfs* causes no alterations in the expression of adjacent genes, mRNA levels of genes adjacent to *mfs* (OG1RF\_10079) in *E. faecalis*  $\Delta mfs$  compared to *E. faecalis* WT OG1RF were measured. The expression of OG1RF\_10076, OG1RF\_10077 and OG1RF\_10082 was not influenced by the deletion of *mfs* (data not shown). The *in vitro* growth of *E. faecalis* OG1RF and  $\Delta mfs$  mutant was similar as measured by OD<sub>600</sub> and CFU counts/ml culture (Figure 11B).

**Figure 11: Characterization of  $\Delta mfs$  deletion mutant from *E. faecalis* OG1RF.**

**(A)** Expression of *mfs* (OG1RF\_10079) and *pyrC* (housekeeping gene) in *E. faecalis* WT OG1RF and  $\Delta mfs$  mutant. Quantitative real-time PCR product was applied to an agarose gel. **(B)** *E. faecalis* OG1RF and  $\Delta mfs$  mutant were grown in BHI under anaerobic conditions and bacterial density was measured using OD<sub>600</sub> and CFU counts/ml culture.

Since the function of *E. faecalis* MFS efflux pump is not known, we measured the resistance of the  $\Delta mfs$  mutant towards different antibiotics, but the deletion did not influence the minimal inhibitory concentration of ampicillin, quinolones (norfloxacin and nalidixic acid), kanamycin, erythromycin, tetracycline, chloramphenicol, nisin, polymyxin B, vancomycin, puromycin and streptomycin (data not shown).

Furthermore, we could not detect any involvement of this transporter in the resistance to bile, antimicrobial peptides (cryptidin-4 and lysozyme) and alkaline or acidic conditions (data not shown). Riboulet-Bisson and colleagues suggested glycerol transport as function of *E. faecalis* MFS transporter, but we could not confirm that the growth of *E. faecalis*  $\Delta mfs$  mutant on glycerol is impaired (data not shown) (Riboulet-Bisson et al., 2009).

Germfree WT and IL-10<sup>-/-</sup> mice were monoassociated with *E. faecalis* WT OG1RF or  $\Delta mfs$  and bacterial colonization density and indicators of chronic, immune-mediated colitis were measured (Figure 7C). After 16 weeks of colonization, IL-10<sup>-/-</sup> mice developed severe inflammation in the distal colon, independent of the *E. faecalis* strain used for monoassociation (OG1RF histopathological score:  $9.6 \pm 1.8$ ,  $\Delta mfs$  histopathological score:  $9.4 \pm 2.0$ ). All WT mice remained disease-free (Figure 12A). It was noticeable that the inflammation in the colon of IL-10<sup>-/-</sup> mice after 16 weeks of colonization was much more pronounced than in the previous monoassociation experiments with *E. faecalis* (chapter 4.1 and 4.3.1). A later colonization time (at the age of 12 weeks compared to the age of 10 weeks) may explain this phenotype.

The colonization density of *E. faecalis* OG1RF and  $\Delta mfs$  mutant was similar as detected by CFU counts in luminal contents from colon (Figure 12C). Histological inflammation in IL-10<sup>-/-</sup> mice was accompanied by elevated spleen weights (Figure 12B) and increased expression of pro-inflammatory cytokines in distal colon tissue (Figure 12D). The expression levels of IFN $\gamma$ , IL-12p40 and IL-17 were similar in both colonization groups, only the expression level of TNF $\alpha$  was increased in *E. faecalis*  $\Delta mfs$  compared to OG1RF monoassociated IL-10<sup>-/-</sup> mice (Figure 12D).

**Figure 12: *E. faecalis* MFS transporter has no impact on the colitogenic activity and colonization density in monoassociated IL-10<sup>-/-</sup> mice.**

Germfree WT and IL-10<sup>-/-</sup> mice were monoassociated with *E. faecalis* WT or  $\Delta mfs$  mutant strain for 16 weeks. **(A)** Histological inflammation in the distal colon. **(B)** Spleen weights. **(C)** *E. faecalis* presence in luminal contents from colon, cecum and ileum according to the CFU counts/ml. **(D)** Cytokine expression in colon tissue sections shown as fold change normalized to cytokine expression levels in WT mice colonized with *E. faecalis* WT.

IFN $\gamma$  and IL-12p40-secretion of re-activated MLN cells was similar for all IL-10<sup>-/-</sup> mice suggesting that MLN cells are fully capable of responding to bacterial antigens independently of the monoassociated *E. faecalis* strain (Figure 13A and B).

**Figure 13: The antigen-specific immune response of re-activated MLN cells was not influenced by the deletion of *mfs*.**

**(A)** IFN<sub>γ</sub> and **(B)** IL-12p40 secretion of MLN cells isolated from *E. faecalis* OG1RF or *Δmfs* mutant monoassociated IL-10<sup>-/-</sup> and WT mice that were re-activated with the corresponding bacterial lysate for 72 hours.

In summary, we tested the functional relevance of *E. faecalis* genes that were up-regulated in response to inflammation, namely genes of the *eut* operon and *mfs* transporter. Despite their massive up-regulation in inflamed monoassociated IL-10<sup>-/-</sup> mice, their deletion had no impact on the colitogenic activity and survival of *E. faecalis* in monoassociated WT and IL-10<sup>-/-</sup> mice. Since the function of *E. faecalis* MFS transporter is not known, we decided to further characterize only *E. faecalis* ethanolamine utilization.

#### 4.4 *E. faecalis* EA utilization has protective functions in a microbial consortium

Despite considerable up-regulation of *eut* genes, the deletion of ethanolamine utilization had no impact on the colitogenic activity of *E. faecalis* in monoassociated mice. To test the hypothesis that *E. faecalis* EA utilization is only important for bacterial fitness in competition with other microbes, we characterized the colitogenic activity of *E. faecalis* *Δeut* mutant strain in the context of a simplified microbial consortium based on seven enteric bacterial strains (SIHUMI).

We colonized germ-free WT and IL-10<sup>-/-</sup> mice with SIHUMI consortium either containing *E. faecalis* WT OG1RF (SIHUMI) or *E. faecalis* *Δeut* (SIHUMI *Δeut*) mutant strain for a period of 16 weeks (Figure 14A). When we introduced the bacterial consortium to germ-free mice, 6 out of 7 species successfully colonized the mouse intestine, as determined by 16S rRNA gene-based quantitative qPCR (Fig. 14B).

*Faecalibacterium prausnitzii* could not be detected by qPCR and droplet digital PCR at any time (Figure 14B, Figure S2A and B) in intestinal content (taken at week 4 and 16 of colonization) and feces (taken at week 2, 4, 8 and 16 of colonization). *Bacteroides (B.) vulgatus* and *Ruminococcus (R.) gnavus* were the most predominant species in the consortium, while the proportion of *E. faecalis* was relatively low (Figure 14B). However, the total bacterial numbers determined by plating on selective agar are comparable to those found for monoassociated *E. faecalis* (Figure 16A). The replacement of *E. faecalis* WT OG1RF strain by the  $\Delta$ *eut* mutant strain resulted in a shift in the bacterial community with a significant increase of *B. vulgatus* relative abundance accompanied by a decrease in *R. gnavus* abundance (Figure 14B).

**Figure 14: Replacement of *E. faecalis* WT OG1RF strain by  $\Delta$ *eut* mutant strain results in a shift in the community of a complex bacterial consortium.**

Germfree WT and IL-10<sup>-/-</sup> mice were colonized with SIHUMI consortium including *E. faecalis* WT (SIHUMI) or  $\Delta$ *eut* strain (SIHUMI  $\Delta$ *eut*) for 16 weeks. **(A)** Experimental setup. **(B)** Relative abundances of SIHUMI bacterial species in luminal colon content by 16S targeted qPCR. *E. coli*, *Escherichia coli*; *E. fae*, *Enterococcus faecalis*; *R. gna*, *Ruminococcus gnavus*; *B. vul*, *Bacteroides vulgatus*; *L. pla*, *Lactobacillus plantarum*; *B. lon*, *Bifidobacterium longum*

While IL-10<sup>-/-</sup> mice colonized with the SIHUMI consortium gradually developed inflammation in the distal colon (SIHUMI histopathological score:  $3.1 \pm 2.3$ ), colitis severity was significantly increased when *E. faecalis* OG1RF was replaced by  $\Delta$ *eut* mutant strain (SIHUMI  $\Delta$ *eut* histopathological score:  $6.1 \pm 1.8$ ) (Figure 15A and B). These results surprisingly suggest protective functions of *E. faecalis* EA utilization in the context of chronic intestinal inflammation. Tissue pathology was accompanied by increased spleen weights in IL-10<sup>-/-</sup> mice colonized with the SIHUMI  $\Delta$ *eut* consortium (Figure 15C). It is noteworthy that the severity of inflammation appeared to be affected by sex, with higher inflammatory scores and spleen weights in female animals (Figure 15A and C). As expected, all colonized WT remained disease-free.

Tissue sections from the distal colon of IL-10<sup>-/-</sup> mice showed high expression of pro-inflammatory cytokines in comparison to WT mice. Tissue expression of TNF and IL-12p40 reflected the degree of histopathology with higher expression levels in SIHUMI  $\Delta$ eut colonized compared to SIHUMI colonized IL-10<sup>-/-</sup> mice. Expression levels of IFN $\gamma$  were similar between SIHUMI and SIHUMI  $\Delta$ eut colonized IL-10<sup>-/-</sup> mice, while IL-17 expression was decreased in SIHUMI  $\Delta$ eut colonized IL-10<sup>-/-</sup> mice (Figure 15D).

**Figure 15: *E. faecalis* ethanolamine utilization has protective functions in IL-10<sup>-/-</sup> mice colonized by a complex bacterial consortium.**

Germfree WT and IL-10<sup>-/-</sup> mice were colonized with SIHUMI consortium including *E. faecalis* WT (SIHUMI) or  $\Delta$ eut strain (SIHUMI  $\Delta$ eut) for 16 weeks. **(A)** Histological inflammation in the distal colon. Male mice are displayed as triangle, female mice as circles. **(B)** Representative hematoxylin/eosin-stained sections of distal colon after 16 weeks of colonization. **(C)** Spleen weight. Male mice are displayed as triangle, female mice as circles. **(D)** Cytokine expression in colon tissue sections shown as fold-change normalized to cytokine expression levels in WT mice colonized with the SIHUMI consortium.

Interestingly, the *E. faecalis*  $\Delta$ eut mutant strain showed an increased colonization density compared to the WT OG1RF strain, as detected by CFU in luminal contents from colon (Figure 16A). However, *E. faecalis* abundance did not correlate with the histopathology score of the distal colon (Figure 16B). The only significant correlation between bacterial abundance and the level of colonic inflammation was detected for *R. gnavus* with a decreased abundance being associated with higher inflammatory scores (Figure 16C).

To address the bacterial antigen-specific immune responses in colonized mice, we isolated MLN cells from IL-10<sup>-/-</sup> mice colonized with SIHUMI or SIHUMI  $\Delta$ eut consortium and re-stimulated them with respective lysates of each of the colonizing species. Unfractionated MLN cells produced high levels of IL-12p40 when stimulated with *E. coli* lysate, while IL-12p40 secretion in response to all other lysates was similar to the negative control. The level of MLN activation was similar for all *E. faecalis* strains (Figure 16D).

**Figure 16: The deletion of ethanolamine utilization increases the colonization rate of *E. faecalis*, but an increased number of *E. faecalis* does not explain the aggravated inflammatory phenotype.**

Germfree WT and IL-10<sup>-/-</sup> mice were colonized with SIHUMI consortium including *E. faecalis* Wt (SIHUMI) or  $\Delta$ eut strain (SIHUMI  $\Delta$ eut) for 16 weeks. **(A)** *E. faecalis* presence in luminal contents from colon as log CFU counts/ml. **(B)** Correlation between *E. faecalis* and **(C)** *R. gnavus* abundance (luminal colon content) and histological scores of distal colon. Light grey indicates SIHUMI experimental group, dark grey indicates SIHUMI  $\Delta$ eut experimental group. **(D)** IL-12p40 secretion of MLN cells isolated from SIHUMI or SIHUMI  $\Delta$ eut colonized mice that were re-activated with the respective bacterial lysate for 72 hours. *E. coli*, *Escherichia coli*; *E. fae*, *Enterococcus faecalis*; *R. gna*, *Ruminococcus gnavus*; *B. vul*, *Bacteroides vulgatus*; *L. pla*, *Lactobacillus plantarum*; *B. lon*, *Bifidobacterium longum*

Since replacement of the WT *E. faecalis* by the mutant  $\Delta$ eut resulted in a more severe inflammatory phenotype, we investigated whether increased inflammation was associated with an enhanced humoral immune response against specific SIHUMI species. It has been demonstrated by others that certain commensal bacteria induce serum IgA responses that confer immunity against polymicrobial sepsis (Wilmore et al., 2018). When we probed lysates of SIHUMI species with sera from SIHUMI or SIHUMI  $\Delta$ eut colonized IL-10<sup>-/-</sup> mice, we observed the highest number of IgA immunoreactive bands for lysates of *B. vulgatus* and *R. gnavus*, the two most prevalent species in colonized mice (Figure 17 and Figure 14B). Similar results have been obtained for serum IgG antibodies (data not shown). *E. faecalis* lysate produced only a weak immunoreactive band. Interestingly, the serum IgA response was not influenced by the level of inflammation, as the number and intensity of immunoreactive bands was similar for lysates probed with SIHUMI or SIHUMI  $\Delta$ eut sera (Figure 17).

**Figure 17: The serum IgA level against *E. faecalis* was not affected by the deletion of ethanolamine utilization.**

Serum IgA against SIHUMI species: Western blots of the indicated bacterial lysates using sera from SIHUMI or SIHUMI  $\Delta$ eut colonized IL10<sup>-/-</sup> mice.

#### 4.5 Complex bacterial consortia interactions reprogram *E. faecalis* gene expression

Since we observed a protective effect of *E. faecalis* EA utilization only in a complex bacterial community and not under conditions of *E. faecalis* monoassociation, we aimed to gain a better understanding of *E. faecalis* gene expression in the presence of other microbes.

We purified *E. faecalis* cells from the colon content of SIHUMI colonized WT and IL-10<sup>-/-</sup> mice using immuno-magnetic separation and performed RNA sequencing (Figure 18A). Transcriptional profiling identified 180 significantly up- and 148 significantly down-regulated genes under inflammatory conditions (Figure S3A, Table S2). The samples clustered according to mouse genotype, as shown by PCA analysis (Figure S3B).

Among the top 20 up-regulated genes, several genes associated with arginine biosynthesis and glycerol metabolism were identified (Figure 18C). Arginine biosynthesis genes have been shown to be up-regulated in lactic acid bacteria in response to acid stress (van de Guchte et al., 2002) and glycerol is an important substrate for *E. faecalis* adaptive fitness during mouse colonization (Lindenstrauss et al., 2014; Muller et al., 2015). Surprisingly, we observed no overlap with the top up-regulated genes of *E. faecalis* isolated from monoassociated mice (Figure 18C and Figure 6C). Additionally, the functional categories enriched among all differentially regulated genes were mainly different between *E. faecalis* monoassociation or in the context of the SIHUMI community (Figure 18B and Figure 6B).

**Figure 18: Complex bacterial consortia interactions reprogram *E. faecalis* gene expression in response to inflammation.**

Luminal *E. faecalis* cells were isolated from the colon of inflamed IL-10<sup>-/-</sup> (n=13) and healthy WT mice (n=6) colonized with SIHUMI consortium (16 weeks of colonization), using immuno-magnetic separation and subjected to RNA sequencing analysis. **(A)** Experimental setup: Transcriptional profiling revealed 180 significantly up-regulated and 148 significantly down-regulated genes in *E. faecalis* isolated from IL-10<sup>-/-</sup> mice compared to *E. faecalis* isolated from WT mice colonized with the SIHUMI consortium. **(B)** Expression distribution of enriched genes for GSEA enriched categories (KEGG) (IL-10<sup>-/-</sup> vs. WT). The gene group highlighted red contains the *eut*-genes. **(C)** Top 20 up-regulated genes in *E. faecalis* isolated from SIHUMI colonized mice (IL-10<sup>-/-</sup> vs. WT). Only annotated genes with known function are shown. Gene functions were assigned according to KEGG database.

In the SIHUMI consortium, *E. faecalis* response to inflammation was characterized by an induction of cellular pathways required for growth and replication including ribosome, aminoacyl tRNA biosynthesis, nucleotide synthesis, pyruvate and propanoate metabolism, ABC transport and fatty acid biosynthesis and metabolism. In contrast to *E. faecalis* monoassociation, inositol phosphate metabolism and the biosynthesis of amino acids were repressed (Figure 18B).

Quorum sensing and glycerolipid metabolism were induced, whereas phosphotransferase systems and starch and sucrose metabolism were repressed in both mono- and complex-association of IL-10<sup>-/-</sup> mice (Figure 18B and Figure 6B). Interestingly, *E. faecalis* isolated from SIHUMI colonized mice showed higher expression of *eut* genes in healthy (Figure 19A) and mildly inflamed (Figure 19B) compared to inflamed animals. This is in line with our finding that *E. faecalis* ethanolamine utilization has a protective function in SIHUMI colonized mice (Figure 15).

**Figure 19: *E. faecalis* *eut* genes are down-regulated in inflamed IL-10<sup>-/-</sup> mice colonized with the SIHUMI consortium.**

**(A)** Differential expression of genes in relation to an inflamed environment is shown for selected *E. faecalis* *eut* genes. **(B)** Differential expression of *eut* genes in *E. faecalis* of a severely inflamed vs. a mildly inflamed environment. The log2 ratios of mean abundance of normalized expression levels are shown; Up regulation is indicated red, down regulation is indicated blue.

In IL-10<sup>-/-</sup> mice colonized with the SIHUMI consortium, we observed a gradient of colitis severity. 6 out of 12 mice had a colitis score < 3 and were defined as mildly inflamed animals, the remaining 6 mice with a colitis score > 3 were defined as severely inflamed animals (Figure 20A). When comparing *E. faecalis* gene expression between severely and mildly inflamed IL-10<sup>-/-</sup> mice, only 11 genes showed statistical significant regulation (Figure S4A and B). In particular, the lipoprotein SpoIIJ (OG1RF\_12576), which has been shown to be important for bile resistance of *E. faecalis* (Dale et al., 2018) and a cell wall surface anchor family protein (OG1RF\_10871), which is associated with *E. faecalis* biofilm formation (Nallapareddy et al., 2006), appeared to be interesting candidates for *E. faecalis* survival and virulence (Figure 20B).

**Figure 20: The severity of intestinal inflammation influences the gene expression of *E. faecalis*.**

**(A)** Histological inflammation scores in the distal colon of SIHUMI colonized IL-10<sup>-/-</sup> mice comparing severely inflamed mice (red) and mildly inflamed mice (blue). **(B)** Significantly differentially regulated genes of *E. faecalis* isolated either from severely inflamed or mildly inflamed SIHUMI colonized IL-10<sup>-/-</sup> mice (up regulation is indicated by grey bar color, down regulation is indicated by black bar color).

When comparing *E. faecalis* transcriptional response to inflammation between bacteria isolated from mono- and complex-associated mice on the gene level, the majority of differentially regulated genes were not shared. This suggests that the bacterial environment reprograms *E. faecalis* gene expression. Only 125 genes were shared between both colonization environments, while 751 genes were exclusively regulated in monoassociation and 203 genes were exclusively regulated in the SIHUMI community (Figure 21A).

In addition, the majority of overlapping genes showed opposite patterns of regulation. Several genes associated with fundamental cellular pathways were down regulated in *E. faecalis* of monoassociated mice, whereas these genes were strongly up regulated in *E. faecalis* of the SIHUMI community. This includes genes associated with the translation apparatus (*lysS*, *trpS2*, *rpmB2*, *rpmH*, *rpsT*, *engA*), RNA synthesis (*rpoZ*), DNA replication (*parE*), citrate cycle (*fdrA*), peptidoglycan biosynthesis (*amiD*, *cwIO*), nucleotide metabolism (*gmk2*, *guaD*, *upp2*) and transport (*ecfA1*, *tagH*, *ctpE*, *secA*) (Figure 21B).

**Figure 21: The majority of regulated genes were not shared between *E. faecalis* isolated from monoassociated and SIHUMI colonized mice.**

**(A)** Venn diagram showing the differentially regulated genes shared (IL-10<sup>-/-</sup> vs. WT) between *E. faecalis* isolated from monoassociated and SIHUMI colonized mice. **(B)** Genes down regulated in monoassociated and up regulated in SIHUMI-associated mice, respectively. The log2 ratios of mean abundances of normalized expression levels are shown (up regulation is indicated red, down regulation is indicated blue). Gene functions were assigned according to KEGG database. Only annotated genes with known function are shown.

*Vice versa*, we observed an up regulation of several stress-response genes in *E. faecalis* of monoassociated mice, including genes that encode for proteases and chaperones (*clpE*, *clpP*, *dnaK*, *dnaJ*, *groEL*, *groES*), a ribosomal stress protein (*rplY*), a detoxifying enzyme (*gloA2*) and proteins associated with DNA repair (*ung*, *dinB2*) and oxidative stress resistance (*gor*) (van de Guchte et al., 2002; Gaca et al., 2012). In addition, genes associated with the biosynthesis of amino acids (*luxS*, *aroA*, *aroB*, *tyrA*, *pheA*), transport (*gidK*, *nhaC*), transcriptional regulation (*glcR*, *lacI*) and a protein homologous to RNA polymerase subunit RpoE were up-regulated in monoassociated *E. faecalis*, but down-regulated in *E. faecalis* colonizing in the SIHUMI consortium (Figure 22).

**Figure 22: General stress-response genes were up-regulated in *E. faecalis* colonizing in monoassociation, but down-regulated in *E. faecalis* colonizing in a bacterial community.**

Differentially regulated genes (IL-10<sup>-/-</sup> vs. WT) overlapping between *E. faecalis* isolated from monoassociated and SIHUMI colonized mice (only genes with opposing regulation pattern are shown). The log2 ratios of mean abundances of normalized expression levels are shown (up regulation is indicated red, down regulation is indicated blue). Gene functions were assigned according to KEGG database, only annotated genes with known function are shown.

#### 4.6 Bacterial consortia interactions reprogram *E. faecalis* colitogenic activity

We next addressed the question of whether the transcriptional differences of *E. faecalis* colonizing in mono- or complex-associated mice have functional consequences by applying the SIHUMI consortium with (SIHUMI) or without *E. faecalis* (SIHUMI -*E. fae*).

WT and IL-10<sup>-/-</sup> mice were colonized at the age of 10 weeks for a period of 4 weeks to analyze early effects at the onset of disease, or 16 weeks to analyze disease progression (Figure 23A). Quantification of bacterial concentrations in colon content showed that the 6 (SIHUMI group) or 5 (-*E. fae* group) colonizing species formed a stable community under gnotobiotic conditions (Figure 23B and C). The relative bacterial abundances were slightly different between the early (4 weeks) and late (16 weeks) colonization period. The proportion of *B. longum* was relatively high after 4 weeks of colonization, but after 16 weeks of colonization *R. gnavus* and *B. vulgatus* were the only dominant species (Figure 23B and C). The absence of *E. faecalis* resulted in changes of the relative abundances of specific SIHUMI species in luminal contents of colon. After 16 weeks of colonization,

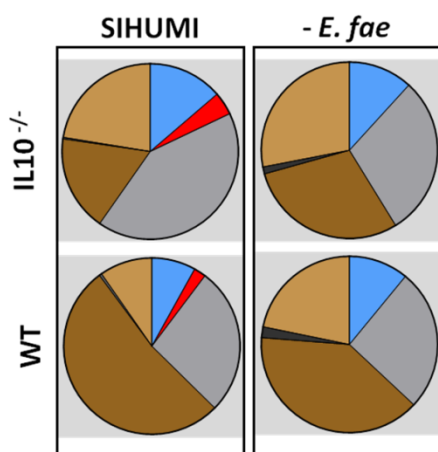

the relative concentrations of *E. coli* and *B. longum* were slightly higher, while *B. vulgatus* concentrations were lower in SIHUMI -*E. fae* colonized mice as compared to SIHUMI colonized mice (Fig. 23C).

A

B

C

**Figure 23: *E. coli* and *B. longum* relative abundances were slightly shifted in SIHUMI colonized mice under omission of *E. faecalis*.**

Germfree IL-10<sup>-/-</sup> and WT mice were colonized with SIHUMI consortium or SIHUMI consortium without *E. faecalis* (-*E. fae*) for a period of 4 and 16 weeks. **(A)** Experimental setup. **(B)** Relative abundances of SIHUMI bacterial species in luminal colon content by 16S targeted qPCR after 4 weeks and **(C)** 16 weeks of colonization. *E. coli*, *Escherichia coli*; *E. fae*, *Enterococcus faecalis*; *R. gna*, *Ruminococcus gnavus*; *B. vul*, *Bacteroides vulgatus*; *L. pla*, *Lactobacillus plantarum*; *B. lon*, *Bifidobacterium longum*

Surprisingly, the colonization of IL-10<sup>-/-</sup> mice with SIHUMI in the absence of *E. faecalis* not only induced inflammation, but resulted in an aggravated inflammatory host response compared to the control. After 16 weeks of colonization, IL-10<sup>-/-</sup> mice colonized with SIHUMI -*E. fae* consortium developed severe inflammation in the distal colon (histopathological score: 4.8 ± 2.4), while the degree of colitis was significantly reduced in IL-10<sup>-/-</sup> mice colonized with SIHUMI in the presence of *E. faecalis* (histopathological score: 2.8 ± 2.5) (Figure 24A and B). After 4 weeks of colonization, IL-10<sup>-/-</sup>

mice showed mild pancolitis independent of the colonizing bacteria. All colonized WT mice remained disease-free (Figure 24A and B).

Again, we observed on average higher histological inflammation in females, suggesting an influence of sex on disease progression in IL-10<sup>-/-</sup> mice colonized with a complex bacterial consortium (Figure 24A). Increased spleen weights and a high level of pro-inflammatory cytokine expression accompanied the histopathological inflammation in IL-10<sup>-/-</sup> mice after a colonization period of 16 weeks (Figure 24C). Of note, the expression of IFN $\gamma$  was significantly higher in IL-10<sup>-/-</sup> mice that were colonized with SIHUMI -*E. fae* consortium compared to SIHUMI colonized mice. TNF and IL-17 expression levels followed the same pattern, whereas IL-12p40 expression was not influenced by the composition of the colonizing consortium (Figure 24D).

**Figure 24: *E. faecalis* has protective functions in IL-10<sup>-/-</sup> mice colonized with a complex bacterial consortium.**

Germfree IL-10<sup>-/-</sup> and WT mice were colonized with SIHUMI consortium or SIHUMI consortium without *E. faecalis* (-*E. fae*) for a period of 4 and 16 weeks. **(A)** Histological inflammation in the distal colon. Male mice are displayed as triangle, female mice as circles. **(B)** Representative hematoxylin/eosin-stained sections of distal colon after 16 weeks of colonization colon. **(C)** Spleen weight. Male mice are displayed as triangle, female mice as circles. **(D)** Cytokine expression in colon

tissue sections shown as fold change normalized to cytokine expression levels in WT mice colonized with SIHUMI consortium.

Since the colonization of IL-10<sup>-/-</sup> mice under omission of *E. faecalis* exacerbated the severity of colitis, another species appears to trigger disease in the SIHUMI setting. The relative abundance of *E. coli* and *B. longum* in large intestinal content were positively correlated with the development of histopathology, while no correlation was observed for *E. faecalis* abundance and colitis activity (Figure 25A and B, Figure S5).

To address the bacterial antigen-specific immune responses of colonized mice, we isolated MLN cells from IL-10<sup>-/-</sup> mice colonized with SIHUMI in the presence and absence of *E. faecalis* and re-stimulated them with respective lysates of each of the colonizing SIHUMI species. After 4 weeks of colonization, the secretion of IFN $\gamma$  and IL-12p40 in response to *E. coli* lysate stimulation was slightly increased in MLN cells isolated from mice colonized with SIHUMI. All other lysates failed to activate the MLN cell cultures (Figure 25C and E). After 16 weeks of colonization, MLN cells produced maximal levels of IFN $\gamma$  and IL-12p40 upon stimulation with *E. coli* lysate, although the relative luminal concentrations of this bacterium were quite low (Figure 23C). The MLN response towards *E. coli* lysate was even more pronounced in MLNs isolated from mice colonized with SIHUMI -*E. fae* consortium (Figure 25D and F), suggesting compensatory mechanisms in the absence of *E. faecalis*.

**Figure 25: MLN response and bacterial abundance indicate *E. coli* as driver of SIHUMI-mediated colitis in IL-10<sup>-/-</sup> mice.**

Germfree IL-10<sup>-/-</sup> and WT mice were colonized with SIHUMI consortium or SIHUMI consortium without *E. faecalis* (SIHUMI -*E. fae*) for a period of 4 and 16 weeks. **(A)** Correlation between *B. longum* and **(B)** *E. coli* abundance (colon and cecum luminal content) and mean histological scores of cecum tip and distal colon. Light grey indicates SIHUMI experimental group, dark grey indicates SIHUMI -*E. fae* experimental group. **(C)** IL-12p40 secretion of MLN cells isolated from SIHUMI or SIHUMI -*E. fae* colonized mice that were re-activated with the respective bacterial lysate after 4 weeks or **(D)** 16 weeks of colonization. **(E)** IFN $\gamma$  secretion of MLN cells isolated from SIHUMI or

SIHUMI *-E. fae* colonized mice that were re-activated with the respective bacterial lysate after 4 weeks or **(F)** 16 weeks of colonization. *E. coli*, *Escherichia coli*; *E. fae*, *Enterococcus faecalis*; *R. gna*, *Ruminococcus gnavus*; *B. vul*, *Bacteroides vulgatus*; *L. pla*, *Lactobacillus plantarum*; *B. lon*, *Bifidobacterium longum*

The level of serum IgA antibodies against SIHUMI species was only slightly influenced by the composition of the bacterial consortium. When we probed lysates of SIHUMI species with sera from SIHUMI or SIHUMI *-E. fae* colonized IL-10<sup>-/-</sup> mice, we observed the highest number of immunoreactive bands for lysates of *B. vulgatus*, *R. gnavus* and *E. coli*. The number and intensity of immunoreactive bands against *E. coli* and *B. vulgatus* lysates were slightly increased when probed with SIHUMI *-E. fae* sera, indicating increased levels of IgA antibodies against these species in mice colonized with SIHUMI in the absence of *E. faecalis* (Figure 26).

**Figure 26: Higher number and intensity of immunoreactive bands (IgA) against *E. coli* and *B. vulgatus* in the absence of *E. faecalis*.**

Serum IgA against SIHUMI species: Western blots of the indicated bacterial lysates using sera from SIHUMI or SIHUMI *-E. fae* colonized IL10<sup>-/-</sup> mice.

A massive pro-inflammatory response of re-activated MLN cells to *E. coli* lysate stimulation (Figure 25D and F) and a positive correlation between histological inflammation and *E. coli* abundance (Figure 25B) points to this bacterium as main driver of SIHUMI-mediated colitis. In addition, the number of IgA (Figure 26) and IgG (data not shown) immunoreactive bands against *E. coli* lysate was increased in gnotobiotic mice colonized with SIHUMI in the absence of *E. faecalis* compared to mice colonized with the whole SIHUMI consortium.

Since it has been shown that *E. faecalis*, which provides protective mechanisms in our experimental environment, can influence the expression of *E. coli* virulence genes (Neuhaus et al., 2017), we analyzed the expression of selected *E. coli* virulence genes via qPCR. Of 9 genes analyzed, only the expression of *E. coli ompC* in IL-10<sup>-/-</sup> mice was significantly reduced when *E. faecalis* was present (Figure S6). *OmpC* encodes for an outer membrane porin that is involved in bacterial multidrug resistance and has been shown to be a major immunogen in human serum (Liu et al., 2012).

#### 4.7 In the absence of *E. coli* other SIHUMI species increase their colitogenic activity

Since our data suggest that *E. coli* is the main colitogenic organism in the SIHUMI consortium, while *E. faecalis* provides protective activity, we wanted to confirm our hypothesis by colonizing germfree WT and IL-10<sup>-/-</sup> mice with the SIHUMI consortium under omission of *E. coli* (SIHUMI -*E. coli*). The corresponding control mice colonized with SIHUMI consortium have already been shown in chapter 4.4.

Mice were colonized at the age of 10 weeks for a period of 16 weeks and bacterial concentrations as well as indicators of chronic, immune-mediated colitis were measured (Figure 27A and B). Quantification of bacterial concentrations in colon content showed that the 5 (SIHUMI -*E. coli*) colonizing species formed a stable community under gnotobiotic conditions (Figure 27B). Interestingly, the omission of *E. coli* caused a large shift in the SIHUMI community with an increase in the proportion of *B. vulgatus* and a decrease in the concentrations of *R. gnavus* and *B. longum* (Figure 27B).

**Figure 27: Omission of *E. coli* results in a major shift of the SIHUMI community.**

Germfree IL-10<sup>-/-</sup> and WT mice were colonized with SIHUMI consortium (see 4.4) or SIHUMI consortium without *E. coli* (-*E. coli*) for a period of 16 weeks. **(A)** Experimental setup. **(B)** Relative abundances of SIHUMI bacterial species in luminal colon content by 16S targeted qPCR. *E. coli*,

*Escherichia coli*; *E. fae*, *Enterococcus faecalis*; *R. gna*, *Ruminococcus gnavus*; *B. vul*, *Bacteroides vulgatus*; *L. pla*, *Lactobacillus plantarum*; *B. lon*, *Bifidobacterium longum*

Contrary to our hypothesis, the SIHUMI *-E. coli* consortium induced a more severe inflammatory phenotype in IL-10<sup>-/-</sup> mice compared to the complete SIHUMI consortium (Figure 28A). After 16 weeks of colonization, IL-10<sup>-/-</sup> mice colonized with SIHUMI *-E. coli* consortium developed severe inflammation in the distal colon (histological score: 5.7 ± 2.5), while the degree of colitis was significantly lower in the SIHUMI control group (histological score: 3.1 ± 2.3; see 4.4) (Figure 28A). Interestingly, in contrast to the colon, the severity of inflammation in the cecum tip of SIHUMI *-E. coli* colonized IL-10<sup>-/-</sup> mice was significantly reduced compared to SIHUMI colonized IL-10<sup>-/-</sup> mice (Figure 28B). All colonized WT mice remained disease free (Figure 28A and B). In SIHUMI colonized IL-10<sup>-/-</sup> mice, on average higher inflammatory scores were observed in females, whereas in SIHUMI *-E.coli* colonized IL-10<sup>-/-</sup> mice no influence of sex on the severity of disease could be observed (Figure 28A and B). Increased spleen weights and a high level of TNFα and IFNγ expression in colon tissue accompanied the histological inflammation in IL-10<sup>-/-</sup> mice (Figure 28C).

**Figure 28: The presence of *E. coli* alleviates the inflammation in the distal colon, but exacerbates the inflammation in the cecum tip in IL-10<sup>-/-</sup> mice colonized with a complex bacterial consortium.**

Germfree IL-10<sup>-/-</sup> and WT mice were colonized with SIHUMI consortium (see 4.4) or SIHUMI consortium without *E. coli* (SIHUMI -*E. coli*) for a period of 16 weeks. **(A)** Histological inflammation in the distal colon or **(B)** cecum tip. Male mice are displayed as triangle, female mice as circles. **(C)** Spleen weight. Male mice are displayed as triangle, female mice as circles. **(D)** TNF $\alpha$  and IFN $\gamma$  expression in colon tissue sections shown as fold change normalized to cytokine expression levels in WT mice colonized with SIHUMI consortium.

Since colonization of IL-10<sup>-/-</sup> mice with the omission of *E. coli* resulted in an exacerbation of the severity of inflammation in the distal colon, *E. coli* appears not to be the trigger of colitis in this environment. In the cecum tip, however, omission of *E. coli* resulted in a less severe inflammatory phenotype, indicating that *E. coli* is in part responsible for the development of cecal inflammation in SIHUMI colonized IL-10<sup>-/-</sup> mice.

To identify the species that drive inflammation development in the absence of *E. coli*, we analyzed bacterial antigen-specific immune responses and serum IgG reactivity to bacterial lysates. As previously shown, MLN cells isolated from IL-10<sup>-/-</sup> mice colonized with SIHUMI produced maximal levels of IFN $\gamma$  and IL-12p40 when stimulated with *E. coli* lysate (Figure 29A and B). In the absence of *E. coli*, however, MLN cells secreted the highest values of IFN $\gamma$  when stimulated with *E. faecalis* lysate, while all other lysates failed to activate the MLN cell cultures (Figure 29A and B).

Sera from SIHUMI colonized IL-10<sup>-/-</sup> mice showed the highest IgG reactivity against *E. coli*, *B. vulgatus* and *R. gnavus* lysates. In the absence of *E. coli* (SIHUMI -*E. coli*), however, no immunoreactive IgG bands against *E. coli* lysate could be observed. Here, we observed an increased number and intensity of immunoreactive bands against *E. faecalis* and *R. gnavus* lysates (Figure 29C). This indicates increased levels of IgG antibodies against these species in mice colonized with SIHUMI in the absence of *E. coli*.

**Figure 29: Increased MLN response and serum IgG reactivity to *E. faecalis* in the absence of *E. coli*.**

Germfree IL-10 $^{-/-}$  and WT mice were colonized with SIHUMI consortium (see 4.4) or SIHUMI consortium without *E. coli* (SIHUMI -*E. coli*) for a period of 16 weeks. **(A)** IFN $\gamma$  and **(B)** IL-12p40 secretion of MLN cells isolated from SIHUMI or SIHUMI -*E. coli* colonized mice that were re-activated with the respective bacterial lysate after 16 weeks of colonization. *E. coli*, *Escherichia coli*; *E. fae*, *Enterococcus faecalis*; *R. gna*, *Ruminococcus gnavus*; *B. vul*, *Bacteroides vulgatus*; *L. pla*, *Lactobacillus plantarum*; *B. lon*, *Bifidobacterium longum* **(C)** Serum IgG against SIHUMI species: Western blots of the indicated bacterial lysates using sera from SIHUMI or SIHUMI -*E. coli* colonized IL10 $^{-/-}$  mice.

*E. faecalis* colonization density was significantly increased in WT, but not in IL-10 $^{-/-}$  mice colonized with SIHUMI -*E. coli* (Figure 30A). The only significant correlation between bacterial abundance and the level of colonic inflammation was detected for *R. gnavus* with a reduced abundance being

associated with higher inflammatory scores (Figure 30B). This is consistent with the results of chapter 4.4.

**Figure 30: Bacterial concentrations do not positively correlate with tissue inflammation.**

Germfree IL-10<sup>-/-</sup> and WT mice were colonized with SIHUMI consortium (see 4.4) or SIHUMI consortium without *E. coli* (SIHUMI -*E. coli*) for a period of 16 weeks. **(A)** *E. faecalis* presence in luminal contents from colon according to the CFU counts/ml. **(B)** Correlation between *R. gnavus* relative abundance (luminal colon content) and histological scores of distal colon. Light grey indicates SIHUMI experimental group, dark grey indicates SIHUMI -*E. coli* experimental group.

## 4. DISCUSSION

In this study, we demonstrate that *E. faecalis* functionally adapts to chronic inflammation, supporting the hypothesis that host-related mechanisms contribute to the colitogenic activity of opportunistic pathogens. *E. faecalis* is a disease-relevant pathobiont and colonization of IBD-related mouse models, such as IL-10<sup>-/-</sup> mice, supports the concept that commensal bacteria harboring pathogenic traits drive chronic inflammation in genetically susceptible but not wild type hosts. In addition to previously identified genes modulating the colitogenic activity of *E. faecalis* (Ocvirk et al., 2015), we performed transcriptional profiling of *E. faecalis* under inflammatory conditions and identified 876 genes to be differentially regulated compared to normal conditions. Among the highest upregulated genes in monoassociated inflamed mice, a gene encoding for a major facilitator superfamily transporter (*mfs*) and genes of the ethanolamine utilization (*eut*) locus were identified. Despite their considerable up-regulation, the deletion of ethanolamine utilization ( $\Delta$ *eutVW*) or *mfs* ( $\Delta$ *mfs*) had no influence on bacterial colonization density and colitogenic activity in monoassociated mice. Interestingly, *E. coli* responds to inflammation in monoassociated IL-10<sup>-/-</sup> mice by the up-regulation of stress response genes, but targeted deletion of these genes aggravated the inflammatory phenotype (Patwa et al., 2011; Tchaptchet et al., 2013). This supports our observation that bacterial adaptation processes correlating with intestinal inflammation are not necessarily harmful for the host. In line with this, we have shown in a previous study that genes that produce two colitis-relevant structures in *E. faecalis* are not transcriptionally regulated in inflamed IL-10<sup>-/-</sup> mice relative to WT controls (Ocvirk et al., 2015).

Although *eut* genes were up-regulated during *E. faecalis* growth in an inflammatory environment, this is not necessarily an indication of *in vivo* utilization of EA. The measurement of luminal intestinal EA allowed us to demonstrate that *E. faecalis* utilizes this substrate *in-vivo* in WT mice and not inflamed IL-10<sup>-/-</sup> mice. However, EA concentrations in inflamed IL-10<sup>-/-</sup> mice were similar for both *E. faecalis* OG1RF and  $\Delta$ *eut* mutant colonization. This is surprising as *E. faecalis* *eut* genes were massively up-regulated in inflamed IL-10<sup>-/-</sup> mice relative to WT controls. This paradox could be explained by limitations of our model as we only analyzed gene expression and not *eut* protein levels. Additional studies to understand *E. faecalis* *eut* gene expression and *in-vivo* EA metabolism are needed.

We provide for the first time evidence for a protective effect of bacterial EA utilization in the context of chronic intestinal inflammation. Using a simplified microbial consortium based on human strains (SIHUMI), we demonstrate that *E. faecalis* EA utilization attenuated colitis in mice colonized with a complex bacterial community. The replacement of *E. faecalis* WT strain by a  $\Delta$ *eut* mutant resulted in exacerbated colitis in SIHUMI colonized IL-10<sup>-/-</sup> mice, as indicated by increased

histological inflammation, increased tissue expression of TNF and IL-12p40 and increased spleen weights. The colonization density of  $\Delta eut$  mutant was slightly increased compared to WT *E. faecalis*. However, the relative abundance of *E. faecalis* did not correlate with the histological inflammation, suggesting that increased *E. faecalis*  $\Delta eut$  numbers do not explain the aggravated inflammatory phenotype. MLN cells secreted high amounts of IL-12p40 in response to *E. coli* lysate, but the highest IgA immunoreactivity was observed for *B. vulgatus* and *R. gnavus*, the two most abundant species. Though, a negative correlation between *R. gnavus* concentration and the severity of intestinal inflammation indicates that this bacterium is not involved in pathogenesis.

Our data indicate that *E. faecalis* is not the driver of inflammation in the SIHUMI community, but modulates disease by interaction with co-colonizing bacteria. The catabolism of EA by *E. faecalis* may prevent the utilization of this metabolite by the more colitogenic species *E. coli*. It has been shown that EA can promote *E. coli* growth and virulence (Bertin et al., 2011; Kendall et al., 2012). Interestingly, a recent study demonstrated that *E. coli* LF82 *eut* operon is upregulated in the presence of bile salts. The authors showed that EA can be utilized as sole source of nitrogen by the LF82 *E. coli* and provides a growth advantage in the intestine of DSS treated mice (Delmas et al., 2019). Yet, the expression of selected *E. coli* LF82 virulence genes (*fliC*, *fimH*, *ompA*, *ompC*) and ethanolamine utilization genes (*eutR*, *eutC*, *eutQ*) was not affected in our model (data not shown) and also the relative abundance of *E. coli* was not increased in the presence of *E. faecalis*  $\Delta eut$  mutant. Additional studies to identify the specific mechanism contributing to the protective effect of *E. faecalis* *eut* gene expression are required.

Our data provide new insights into the role of EA utilization in microbiota-host interactions. EA plays a well-recognized role in host adaption and virulence of enteric pathogens including EHEC, *Salmonella* and *Listeria monocytogenes* (Joseph et al., 2006; Bertin et al., 2011; Kendall et al., 2012; Luzader et al., 2013; Anderson et al., 2015). In contrast, we show that *E. faecalis* EA utilization has a protective function in IL-10<sup>-/-</sup> mice. These discrepancies might arise from differences in bacterial physiology and pathogenicity. The pathogen salmonella requires alternative electron acceptors released from inflamed host tissue for EA utilization (Price-Carter et al., 2001; Thiennimitr et al., 2011), whereas *E. faecalis* can grow anaerobically on EA in the absence of alternative electron acceptors (Garsin, 2010). In addition, others have demonstrated a protective effect of EA utilization by opportunistic pathogens as well. The metabolism of EA resulted in reduced virulence together with a delayed onset of disease in a hamster model of *Clostridium difficile* infection (Nawrocki et al., 2018). Furthermore, EA utilization by commensal *E. coli* isolates allowed them to outcompete the pathogen EHEC (Rowley et al., 2018).

Consistent with our data, the colonization efficiency of *E. faecalis*  $\Delta$ eutVW in the murine gastrointestinal tract was increased relative to the WT strain (Kaval et al., 2018). This stands in contrast to enteric pathogens, where the loss of EA utilization resulted in a competitive disadvantage (Bertin et al., 2011; Thiennimitr et al., 2011; Anderson et al., 2015). In *Caenorhabditis elegans*, an *E. faecalis* eut mutant was attenuated in virulence, but in this host some *E. faecalis* strains are regarded as pathogenic organisms resulting in the death of infected nematodes (Maadani et al., 2007). The interesting correlation between bacterial lifestyle and the role of EA utilization for bacterial survival and virulence awaits further investigation.

To the best of our knowledge, this is the first published study that analyzed the influence of co-colonization with a bacterial consortium on gene expression and function of an opportunistic pathogen. Most importantly, we demonstrate that complex bacterial consortia interactions reprogram the gene expression profile and the colitogenic activity of *E. faecalis* towards a protective function. Transcriptional interactions between bacteria have already been illustrated for two members of the dominant gut bacterial phyla. *Eubacterium rectale* and *Bacteroides thetaiotaomicron* adapt their profile of utilized substrates in response to the co-colonizing species in gnotobiotic mice (Mahowald et al., 2009). In addition, Plichta et al. demonstrated transcriptional species-specific interactions in a complex bacterial community with central metabolisms being strongly affected by coexistence with other microbes (Plichta et al., 2016). Using immuno-magnetic separation, we were able to isolate *E. faecalis* cells from SIHUMI colonized mice. This allowed us to study for the first time the transcriptional response of an opportunistic pathogen to host inflammation depending on the microbial environment. Interestingly, the majority of regulated genes were not shared between *E. faecalis* colonizing in monoassociation or in the SIHUMI community. This shows that *E. faecalis* transcriptionally adapts to the co-colonizing microbes.

In monoassociated IL-10<sup>-/-</sup> mice, *E. faecalis* gene expression was characterized by an enrichment of functions important for bacterial stress adaption. General stress-response genes, amino acid biosynthesis genes and genes involved in the utilization of alternative carbon sources were up regulated. A similar regulation pattern has been observed by others analyzing *E. faecalis* transcriptome during mammalian infection. For instance, the intraperitoneal transcriptome of *E. faecalis* in gnotobiotic mice is characterized by the up-regulation of stress-response genes and a metabolic adaption to an inflamed environment (Muller et al., 2015). Frank et al. demonstrated that *E. faecalis* cells undergo transcriptional adaption and exist in a stringent response state in a rabbit subdermal abscess model (Frank et al., 2014). The stringent response, a bacterial stress adaption mechanism, is characterized by the repression of fundamental cellular pathways, whereas amino acid biosynthesis genes and stress-survival genes are strongly induced. In addition,

metabolic rearrangements including the utilization of alternative carbon sources are a hallmark of the stringent response (Traxler et al., 2008; Gaca et al., 2012).

In co-colonization with other microbes, however, *E. faecalis* gene expression in inflamed mice is not primarily characterized by the induction of stress-response pathways, but rather by an enrichment of pathways important for bacterial growth and replication. Although some genes important for bacterial adaption to environmental stress were up regulated (e.g. arginine deaminase pathway genes, *opuC*, *phrB*) (van de Guchte et al., 2002; Maadani et al., 2007), the transcriptional profile does not indicate a stringent response state as observed in monoassociated *E. faecalis*. Fundamental cellular pathways like replication and translation were induced and the expression of general stress-response genes like *clpE*, *clpP*, *dnaK*, *dnaJ*, *groEL*, *groES* was repressed (Giard et al., 2001; Gaca et al., 2012; Muller et al., 2015).

Previous studies analyzing *E. faecalis* function in chronic inflammation were conducted in monoassociated IL-10<sup>-/-</sup> mice and revealed a colitogenic behavior (Balish and Warner, 2002; Kim et al., 2005; Steck et al., 2011; Ocvirk et al., 2015). By characterizing *E. faecalis* as part of a microbial consortium, we are adding new knowledge to the complex interdependence of opportunistic pathogens, the genetically predisposed host and the microbial environment. Colonization of IL10<sup>-/-</sup> mice with SIHUMI under omission of *E. faecalis* resulted in a more severe phenotype as indicated by the histological inflammation, spleen weights and the pro-inflammatory cytokine expression in colon tissue. This supports the hypothesis that *E. faecalis* provides protective mechanisms in complex consortia by the utilization of EA. A massive pro-inflammatory response of re-activated MLN cells to *E. coli* lysate stimulation and a positive correlation between histopathology and *E. coli* abundance pointed to this bacterium as main driver of SIHUMI mediated colitis.

Surprisingly, colonization of IL-10<sup>-/-</sup> mice with SIHUMI under omission of supposedly colitogenic *E. coli* resulted again in a more severe inflammatory phenotype in colon. This suggests that the colitogenic activity of *E. coli* is compensated by other members of the consortium. The protective function of *E. coli* presence was only observed in colon, not in cecum, where the absence of *E. coli* led to less severe inflammation. Kim and colleagues showed that *E. coli*-driven inflammation is most prevalent in cecum in IL-10<sup>-/-</sup> mice (Kim et al., 2005) which supports our finding that *E. coli* is partly responsible for the development of cecal but not colonic inflammation in SIHUMI colonized IL-10<sup>-/-</sup> mice.

Bacterial antigen-specific immune responses by MLN cells and serum IgG reactivity suggest *E. faecalis* as the species that mainly triggers the inflammation in colon when *E. coli* is not present. This stands in marked contrast to our previous experiment, where we observed a protective effect of *E. faecalis* in SIHUMI colonized mice. This indicates a reciprocal interaction between the opportunistic

pathogens *E. faecalis* and *E. coli*. In the absence of one, the other becomes more colitogenic than in the presence of both. In conclusion, our experiments with the SIHUMI consortium emphasize the dualistic character of opportunistic pathogens and show that the colitogenic function of a bacterial strain is not only defined by its gene repertoire, but also by co-colonizing microbes.

Some examples can be found in literature that microbe-host interactions can be influenced by the microbial environment. Simultaneous colonization of IL-10<sup>-/-</sup> mice with *E. coli* and *E. faecalis* resulted in more aggressive colitis as compared to disease induced by each species individually (Kim et al., 2007). *Helicobacter hepaticus*, an opportunistic mouse pathogen, causes disease in mouse models of experimental colitis in combination with a complex SPF microbiota (Cahill et al., 1997). *H. hepaticus* and *Lactobacillus reuteri* do not induce disease in monoassociated IL-10<sup>-/-</sup> mice, but when both strains are used in a dual-association system, they induce severe colitis (Whary et al., 2011). This indicates that *H. hepaticus* requires the presence of other microbes to trigger or exacerbate disease in susceptible IL-10<sup>-/-</sup> mice.

The presence of *Klebsiella pneumoniae* and *Proteus mirabilis*, both opportunistic pathogens associated with nosocomial infections, correlated with colitis in a mouse model of ulcerative colitis. The infection of Rag2-deficient and WT mice with *K. pneumoniae*, *P. mirabilis*, or a combination of both strains triggered inflammation in the presence of a complex specific-pathogen free (SPF) microbiota. However, *K. pneumoniae* and *P. mirabilis* dual-association of germfree mice did not result in the development of colitis (Garrett et al., 2010).

Similarly, in the SCID mouse model, segmented filamentous bacteria were only effective in triggering intestinal inflammation in combination with a complex SPF microbiota (Stepankova et al., 2007). Vice versa, *E. coli* induces colitis in gnotobiotic IL-2-deficient mice, but co-association with *B. vulgatus* prevents colitis development (Waidmann et al., 2003). In addition, Ganesh and colleagues were able to demonstrate that *Akkermansia muciphila*, a mucin-degrading commensal, exacerbates *S. typhimurium*-induced intestinal inflammation in gnotobiotic mice by disturbance of the host-mucus homeostasis (Ganesh et al., 2013).

## 5. CONCLUSION & PERSPECTIVE

In summary, we demonstrate that *E. faecalis* gene expression and colitogenic activity is influenced by co-colonizing microbes. This emphasizes the use of microbial consortia to investigate bacterial functions that may not be apparent in monoassociated studies. The protective effect of *E. faecalis* EA utilization was only apparent in SIHUMI colonized mice, not in monoassociation. Further work is needed to identify the mechanisms contributing to the protective effect of *E. faecalis eut* gene expression. A first step would be to measure EA concentrations in luminal content of mice colonized with SIHUMI, including either *E. faecalis* OG1RF or  $\Delta eut$  mutant. This would clarify whether *E. faecalis* utilizes EA in co-colonization with the consortium and whether this prevents the utilization of EA by another member of the bacterial community.

We showed that in the absence of the opportunistic pathogens *E. faecalis* or *E. coli*, other SIHUMI species increase their colitogenic potential, leading to a worsening of the inflammatory phenotype. This indicates that biodiversity is important even on such a small scale and highlights bacterial interaction and competition for the maintenance of a homeostatic ecosystem. Our data suggest that it is important to study interactions between intestinal species in detail, as bacteria can change their colitogenic potential depending on co-colonizing bacteria. Future experiments with minimal bacterial consortia may help to dissect the complex disease-relevant microbe-microbe and microbe-host interactions in chronic intestinal inflammation. A reasonable approach to unravel those complex mechanisms would be to reduce the diversity and colonize susceptible mice with all possible combinations of a minimal consortium consisting of only *E. faecalis*, *E. coli* and an obligate anaerobic species like *B. vulgatus*.

The investigation of disease progression and the measurement of immune cell subsets and antigen-specific immune responses can contribute to a better understanding of the complex interplay between microbes and the host's immune system. In addition, the generation of fluorescence-labeled bacterial species would make it possible to easily determine absolute bacterial counts and their specific intestinal location within the consortium.

Transcriptional interactions between members of the minimal bacterial consortium could be investigated by the use of metatranscriptomics. Based on the transcriptomic data set, targeted deletion of bacterial genes and the targeted measurement of metabolites, like short-chain fatty acids, bile acids and EA would give functional insight into microbe-microbe interactions relevant for the development of chronic inflammation.

Starting with a simple system and gradually adding more complexity is a complementary approach to screening for disease-associated microbial signatures in complex ecosystems by sequencing

techniques. Only a combination of both approaches will finally contribute to a basic understanding of the pathogenesis of human IBD.

## ADDENDUM

### Supplementary figures

**Figure S1**

**(A)** Differentially expressed genes in *E. faecalis* isolated from monoassociated IL-10<sup>-/-</sup> (KO) vs. WT mice. MA plot shows the distribution of log<sub>2</sub> fold changes in gene expression, the average of the counts normalized by size factor is shown on the x-axis. Each gene is represented with a dot. Genes with an adjusted p-value below 0.05 are indicated in red. **(B)** PCA plot showing sample-to-sample distances according to their gene expression profiles for *E. faecalis* isolated from monoassociated IL-10<sup>-/-</sup> vs. WT mice.

**Figure S2**

Droplet digital PCR: PCR positive droplets are color-coded in blue, primers are targeted against *F. prausnitzii* 16S rRNA. **(A)** Standard curve with *F. prausnitzii* DNA isolated from culture, DNA concentration per reaction (blue). **(B)** Droplet digital PCR reaction with 50 ng of total DNA isolated from luminal colon content of germfree (neg.) and SIHUMI colonized IL-10<sup>-/-</sup> (#1-4) and WT (#5-8) mice after a colonization period of 4 (#1,2,5,6) and 16 weeks (#3,4,7,8).

**Figure S3**

Differentially expressed genes in *E. faecalis* isolated from SIHUMI colonized IL-10<sup>-/-</sup> (KO) vs. WT mice. **(A)** MA plot shows the distribution of log<sub>2</sub> fold changes in the gene expression, the average of the counts normalized by size factor is shown on the x-axis. Each gene is represented with a dot. Genes with an adjusted p-value below 0.5 are indicated in red. **(B)** PCA plot showing sample-to-sample distances according to their gene expression profiles.

**Figure S4**

Differentially expressed genes in *E. faecalis* isolated from SIHUMI colonized severely inflamed IL-10<sup>-/-</sup> vs. mildly inflamed IL-10<sup>-/-</sup> mice. **(A)** MA plot shows the distribution of log<sub>2</sub> fold changes in the gene expression, the average of the counts normalized by size factor is shown on the x-axis. Each gene is represented with a dot. Genes with an adjusted p-value below 0.5 are indicated in red. **(B)** PCA plot showing sample-to-sample distances according to their gene expression profiles.

**Figure S5**

Germfree IL10<sup>-/-</sup> and WT mice were colonized with SIHUMI consortium or SIHUMI consortium without *E. faecalis* (-*E. fae*). Correlation between *E. faecalis* abundance (colon and cecum luminal content) and mean histological scores of cecum tip and distal colon after 16 weeks of colonization.

**Figure S6**

Germfree IL10<sup>-/-</sup> and WT mice were colonized with SIHUMI consortium or SIHUMI consortium without *E. faecalis* (-*E. fae*) for a period of 16 weeks. Expression of selected *E. coli* LF82 virulence genes shown as fold change normalized to expression levels in WT mice colonized with SIHUMI consortium.

## List of figures

Figure 1: Microbe-Host interactions in IBD pathogenesis.....	5
Figure 2: Impact of microbial colonization on disease development in gnotobiotic IL-10 <sup>-/-</sup> mice.....	11
Figure 3: Mutagenesis strategy .....	21
Figure 4: <i>E. faecalis</i> induces colitis in IL-10 <sup>-/-</sup> mice between 12 and 20 weeks of colonization. ....	33
Figure 5: Spleen and MLN weights increase with the degree of intestinal inflammation. ....	34
Figure 6: <i>E. faecalis</i> adapts transcriptionally to chronic colitis in monoassociated IL-10 <sup>-/-</sup> mice. ....	36
Figure 7: <i>E. faecalis</i> <i>eut</i> operon and <i>mfs</i> gene are highly up-regulated in inflamed IL-10 <sup>-/-</sup> mice. ....	37
Figure 8: <i>E. faecalis</i> $\Delta$ <i>eut</i> mutant is not able to utilize EA as carbon source. ....	38
Figure 9: Ethanolamine utilization has no influence on the colitogenic activity and colonization density of <i>E. faecalis</i> in monoassociated IL-10 <sup>-/-</sup> mice. ....	39
Figure 10: IL-12p40 secretion of re-activated MLN cells is decreased for <i>E. faecalis</i> $\Delta$ <i>eut</i> mutant. ....	40
Figure 11: Characterization of $\Delta$ <i>mfs</i> deletion mutant from <i>E. faecalis</i> OG1RF.....	41
Figure 12: <i>E. faecalis</i> MFS transporter has no impact on the colitogenic activity and colonization density in monoassociated IL-10 <sup>-/-</sup> mice.....	43
Figure 13: The antigen-specific immune response of re-activated MLN cells was not influenced by the deletion of <i>mfs</i> . ....	44
Figure 14: Replacement of <i>E. faecalis</i> WT OG1RF strain by $\Delta$ <i>eut</i> mutant strain results in a shift in the community of a complex bacterial consortium. ....	45
Figure 15: <i>E. faecalis</i> ethanolamine utilization has protective functions in IL-10 <sup>-/-</sup> mice colonized by a complex bacterial consortium.....	46
Figure 16: The deletion of ethanolamine utilization increases the colonization rate of <i>E. faecalis</i> , but an increased number of <i>E. faecalis</i> does not explain the aggravated inflammatory phenotype. ....	47
Figure 17: The serum IgA level against <i>E. faecalis</i> was not affected by the deletion of ethanolamine utilization.....	48
Figure 18: Complex bacterial consortia interactions reprogram <i>E. faecalis</i> gene expression in response to inflammation.....	50
Figure 19: <i>E. faecalis</i> <i>eut</i> genes are down-regulated in inflamed IL-10 <sup>-/-</sup> mice colonized with the SIHUMI consortium. ....	51
Figure 20: The severity of intestinal inflammation influences the gene expression of <i>E. faecalis</i> . ....	52
Figure 21: The majority of regulated genes were not shared between <i>E. faecalis</i> isolated from monoassociated and SIHUMI colonized mice. ....	53
Figure 22: General stress-response genes were up-regulated in <i>E. faecalis</i> colonizing in monoassociation, but down-regulated in <i>E. faecalis</i> colonizing in a bacterial community. ....	54

Figure 23: <i>E. coli</i> and <i>B. longum</i> relative abundances are slightly shifted in SIHUMI colonized mice under omission of <i>E. faecalis</i> .....	55
Figure 24: <i>E. faecalis</i> has protective functions in IL-10 <sup>-/-</sup> mice colonized with a complex bacterial consortium. ....	56
Figure 25: MLN response and bacterial abundance indicate <i>E. coli</i> as driver of SIHUMI-mediated colitis in IL-10 <sup>-/-</sup> mice. ....	58
Figure 26: Higher number and intensity of immunoreactive bands (IgA) against <i>E. coli</i> and <i>B. vulgatus</i> in the absence of <i>E. faecalis</i> . ....	59
Figure 27: Omission of <i>E. coli</i> results in a major shift of the SIHUMI community. ....	60
Figure 28: The presence of <i>E. coli</i> alleviates the inflammation in the distal colon, but exacerbates the inflammation in the cecum tip in IL-10 <sup>-/-</sup> mice colonized with a complex bacterial consortium.....	61
Figure 29: Increased MLN response and serum IgG reactivity to <i>E. faecalis</i> in the absence of <i>E. coli</i> . ....	63
Figure 30: Bacterial concentrations do not positively correlate with tissue inflammation. ....	64
Figure S1 .....	72
Figure S2 .....	72
Figure S3 .....	73
Figure S4 .....	73
Figure S5 .....	74
Figure S6 .....	74

## List of tables

Table 1. Companies purchasing experimental material used for the thesis.....	16
Table 2. Bacterial strains used in this study .....	17
Table 3. Composition of the bacterial consortium in the respective experimental groups .....	19
Table 4. Primers used for the generation of the $\Delta mfs$ deletion mutant from <i>E. faecalis</i> OG1RF .....	20
Table 5. Species specific 16S-targeted primers and UPL probes used for bacterial community analysis .....	23
Table 6. Primers and corresponding UPL probes used for bacterial gene expression analysis .....	25
Table 7. Dehydration and paraffin embedding of fixed tissue sections.....	28
Table 8. Deparaffinization, rehydration and H&E staining of tissue sections (LeicaST5020) .....	29
Table 9. Primers and corresponding UPL probes used for mouse gene expression analysis .....	30
Table S1: Significantly differentially regulated genes between <i>E. faecalis</i> isolated from monoassociated IL-10 <sup>-/-</sup> vs. WT mice.....	75
Table S2: Significantly differentially regulated genes between <i>E. faecalis</i> isolated from SIHUMI colonized IL-10 <sup>-/-</sup> vs. WT mice.....	107

**List of abbreviations**

$\Delta eut$	<i>E. faecalis</i> OG1RF <i>eutV</i> and <i>eutW</i> double deletion mutant
$\Delta mfs$	<i>E. faecalis</i> OG1RF <i>mfs</i> deletion mutant
AdoCbl	adenosylcobalamin
AIEC	adherent and invasive <i>E. coli</i>
AMP	antimicrobial peptide
ATG16L1	autophagy-related protein 16-1
<i>B. longum</i>	<i>Bifidobacterium longum</i>
<i>B. vulgatus</i>	<i>Bacteroides vulgatus</i>
BHI	brain heart infusion
CD	cluster of differentiation
CD	Crohn's disease
cDNA	complementary DNA
CEACAM6	carcinoembryonic antigen-related cell adhesion molecule 6
CFU	colony forming units
Cm	chloramphenicol
Ct	threshold cycle
DC	dendritic cell
ddPCR	digital droplet PCR
DSS	dextran sulfate sodium
DTT	dithiothreitol
<i>E. coli</i> ; <i>E. col</i>	<i>Escherichia coli</i>
<i>E. faecalis</i> ; <i>E. fae</i>	<i>Enterococcus faecalis</i>
EA	ethanolamine
EDTA	ethylenediaminetetraacetic acid
EHEC	enterohemorrhagic <i>E. coli</i>
ELISA	enzyme linked immunosorbent assay
epa	enterococcal polysaccharide antigen
ER	endoplasmatic reticulum
Eut	ethanolamine utilization
<i>eut</i>	ethanolamine utilization genes
<i>F. prausnitzii</i>	<i>Faecalibacterium prausnitzii</i>
FMT	fecal microbiota transplantation
gDNA	genomic DNA
GeIE	gelatinase E
GF	germfree
GI	gastrointestinal
GSEA	<i>Gene Set Enrichment Analysis</i>
HLA	human leukocyte antigen
IBD	inflammatory bowel diseases
IEC	intestinal epithelial cells
IFN	interferon
IgA	immunoglobulin A
IgG	immunoglobulin G
IL	interleukin

IL-10 <sup>-/-</sup>	IL-10-deficient mouse
IMS	immunomagnetic separation
IPTG	Isopropyl-β-D-thiogalactopyranosid
IRGM	immunity-related GTPase family M protein
KEGG	Kyoto Encyclopedia of Genes and Genomes
<i>Lb. plantarum</i>	<i>Lactobacillus plantarum</i>
LB	lysogeny broth
MAPK	mitogen-activated protein kinase
<i>mfs</i>	major facilitator superfamily transporter gene
MFS	major facilitator superfamily transporter protein
MLN	mesenteric lymph node
NCF4	neutrophil cytosol factor 4
NF- κB	nuclear factor-κB
NOD2	nucleotide-binding oligomerization domain 2
OD	optical density
ON	over night
ORF	open reading frame
PBS	phosphate-buffered saline
PCA	principal component analysis
PCR	polymerase chain reaction
PRR	pattern recognition receptor
PVDF	polyvinylidene difluoride
qPCR	real-time quantitative PCR
<i>R. gnavus</i>	<i>Ruminococcus gnavus</i>
RNAseq	RNA sequencing
rRNA	ribosomal RNA
<i>S. Typhimurium</i>	<i>Salmonella Typhimurium</i>
SCFA	short-chain fatty acids
SCID	severe combined immunodeficiency
SDS-PAGE	discontinuous denaturing polyacrylamid gel electrophoresis
SIHUMI	simplified human microbiota consortium
SNP	single nucleotide polymorphism
SPF	specific pathogen free
TBST	Tris-buffered saline with Tween20
TLR	toll-like receptor
TM-IEC C1galt1(-/-)	mice deficient in core 1-derived O-glycans
TNBS	2,4,6-trinitrobenzene sulfonic acid
TNF	tumor necrosis factor
Treg cells	T-regulatory cells
UC	Ulcerative colitis
UPL	universal probe library
WCA	Wilkins-Chalgren-Agar
WT	wild type
X-Gal	5-Brom-4-chlor-3-indoxyl-β-D-galactopyranosid

## Acknowledgements

Abschließend möchte ich nicht nur den Menschen danken, die mich bei meiner Arbeit unterstützt haben, sondern auch denen die mich von meiner Arbeit abgelenkt haben, und so entscheidend zum Gelingen der Promotion beigetragen haben.

Ich möchte meinem ersten Gutachter Dirk Haller für die die vielfältigen Entfaltungsmöglichkeiten bedanken, die mir die Arbeit an seinem Lehrstuhl ermöglicht hat. Vielen Dank für die zahlreichen kritischen und konstruktiven Diskussionen und die hervorragende technische und finanzielle Unterstützung.

Ganz besonderer Dank geht an meine Mentorin Irina Sava, die mich herzlich in das Enterokokken Team aufgenommen hat, mir das nötige Rüstzeug in die Hand gegeben hat und mich stets mit gutem Rat unterstützt hat. Danke liebe Irina, auf noch viele schöne Abende mit gutem Essen und guten Gesprächen.

Ich danke Herrn Prof. Dr. Wolfgang Liebl für die Übernahme des Koreferats. Bei Herrn Prof. Dr. Scherer bedanke ich mich für die Übernahme des Vorsitzes der Prüfungskommission.

Großer Dank gilt auch Prof. Dr. Balfour Sartor und seiner gesamten Arbeitsgruppe an der University of North Carolina. Vielen Dank für die erfolgreiche Kollaboration und die Gastfreundschaft in Chapel Hill! Besonders danken möchte ich in diesem Zusammenhang Jeremy Herzog, Michael Shanahan und Lisa Holt, die durch ihre tatkräftige Unterstützung die Experimente vor Ort erst möglich gemacht haben.

Meinen weiteren Dank richte ich an die Menschen, die mit ihrer Expertise und Unterstützung entscheidend zum Gelingen dieser Arbeit beigetragen haben: Luis Felipe Romero Saavedra, Klaus Neuhaus, Josef Sperl, Karin Kleigrew, Kurt Gedrich.

Tausend Dank an meine lieben Kollegen und Kolleginnen am Lehrstuhl für Ernährung und Immunologie, von denen einige zu Freunden wurden. Ihr habt mich in den letzten Jahren immer bereitwillig mit Ratschlägen, tatkräftiger Hilfe, Diskussionsbeiträgen und vor allem mit viel Spaß und Freude unterstützt: Sarah Just, Elena Lobner, Valentina Schüppel, Amira Metwaly, Sören Ocvirk, Brita Sturm, Jelena Calasan, Sevana Khaloian, Sigrid Kisling, Ingrid Schmöller, Nina Heppner, Silvia Pitariu, Alexandra Buse, Sandra Fischer, Simone Daxauer, Melanie Klein, Stephanie Ewald, Alexander Wolf, Olivia Coleman, Nadine Waldschmitt, Monika Schauback, Elisabeth Gleisinger, Adam Sorbie, Patricia Richter, Monika Bazanella, Janine Kövilein, Mohamed Ahmed, Miriam Ecker, Eva Rath, Silke Kiessling, Malwine Solecki, Sonja Böhm, Caroline Ziegler, Ilias Lagkouvardos, Gabriele Hörmannspurger, Thomas Clavel, Ludovica Butto.

Lieber Nico, danke für den stets exzellenten technischen Rat und für die stetige Bereitschaft zu einem Feierabendbierchen!

Besonderen Dank auch an meine Freunde, meine Familie und meinen Partner, die mir immer zur Seite gestanden sind.

## Publications and presentations

### Peer-reviewed original research articles

Ocvirk, S., Sava, I.G., **Lengfelder, I.**, Lagkouvardos, I., Steck, N., Roh, J.H., Tchaptchet, S., Bao, Y., Hansen, J.J., Huebner, J., Carrol, I.M., Murray B.E., Sartor R.B., Haller, D. (2015). Surface-Associated Lipoproteins Link *Enterococcus faecalis* Virulence to Colitogenic Activity in IL-10-Deficient Mice Independent of Their Expression Levels. *PLoS Pathog* 11(6), e1004911. doi: 10.1371/journal.ppat.1004911.

### Original research articles in preparation

**Lengfelder, I.**, Sava, I.G., Hansen, J.J., Kleigrewe, K., Herzog, J., Neuhaus, K., Hofmann, T., Sartor, R.B., Haller, D. Complex bacterial consortia reprogram the colitogenic activity of *Enterococcus faecalis* in a gnotobiotic mouse model of chronic, immune-mediated colitis. Accepted at Frontiers in Immunology.

### Oral presentations

- Beyond the intestinal microbiome-- From signatures to therapy, Hannover (2014)
- 7th Seeon conference: Microbiota, Probiota and Host, Seeon (2014)
- External workshop of German Research Foundation (DFG) research training group GRK 1482, Spitzingsee (2015)
- Science Camp of German Research Foundation (DFG) research training group GRK 1482, Seeon (2017)
- 5th Joint Conference of the DGHM & VAAM, Würzburg (2017)

### Poster presentations

- Beyond the intestinal microbiome-- From signatures to therapy, Hannover (2014)
- 52. Wissenschaftlicher Kongress der DGE: Ernährung und Umwelt – Determinanten unseres Stoffwechsels, Halle (2015)
- 71. Jahrestagung der Deutschen Gesellschaft für Hygiene und Mikrobiologie, Göttingen (2019)
- 8th Seeon conference: From Sequencing to Function, Seeon (2015)
- 11th Seeon conference: From Sequencing to Function, Seeon (2018)

## Curriculum vitae

### Personal information:

Surname/ First names Lengfelder Isabella Brigitta  
 Date of birth 06.03.1989  
 Nationality German  
 Email isabella.lengfelder@hotmail.de  
 linkedin <https://www.linkedin.com/in/isabella-lengfelder-755065173/>

### Work experience:

04/2014 – 12/2018 Research associate, Technische Universität München  
 Chair of Nutrition and Immunology  
 Title of PhD thesis:  
 Complex bacterial consortia reprogram the colitogenic activity of  
*Enterococcus faecalis* in a gnotobiotic mouse model of chronic, immune-  
 mediated colitis  
 11/2011 – 02/2012 Research assistant, University Hospital Würzburg  
 Institute for Clinical Neurobiology

### Education:

04/2014 – 05/2017 Scholarship, Graduiertenkolleg 1482  
 10/2008 – 11/2013 Studies in Biology, Universität Würzburg  
 Degree: Master of Science, with distinction  
 Master thesis (Chair of Microbiology): The role of the ER-mitochondrial  
 interface (MAM) on infection with *Simkania*  
 Degree: Bachelor of Science, with distinction  
 Bachelor thesis (Institute for Clinical Neurobiology): Parkin and its role in the  
 $\text{Ca}^{2+}$ -homeostasis of neuronal cells  
 09/1999 – 07/2008 High school Gabrieli-Gymnasium-Eichstätt
